Professor Greenspan (Ph.D., 1966, in Nuclear Science and Engineering from Cornell University, Ithaca, N.Y., USA) retired from the Department of Nuclear Engineering of the University of California at Berkeley (UCB) in 2014 but served as a Professor in the UCB Graduate School until 2019. He has nearly 60 years of nuclear energy related research experience starting in 1961 as an M.Sc. student at the Department of Nuclear Engineering of the Israel Institute of Technology. His research spans a wide range of nuclear engineering related disciplines including: theoretical and experimental reactor physics; computational methods development including development of new optimization methods for determining the minimum critical mass and for finding optimal design of radiation shields, fusion reactor blankets and medical installations; conception and analysis of advanced fusion fuel cycles and of fusion-fission hybrid reactors; as well as advanced fission reactors and nuclear fuel-cycle conception, design and analysis. The latter activity was the focus of his research during the last twenty-five years. The thrust of this

research is improving sustainability of nuclear energy along with improving economics, safety, and proliferation resistance. He has been the Principal Investigator on studies of dozens of advanced nuclear systems, including those corresponding to Generation-IV reactors and to Small Modular Reactors (SMRs). He was one of the early advocates of SMRs and led a multi-institutional international team that developed a preliminary conceptual design of the Encapsulated Nuclear Heat Source (ENHS)—an innovative nuclear battery-type SMR that is free of pumps, pipes and valves in the primary reactor system. The advanced reactor technologies addressed in his research include: heavy water reactors, pressurized and boiling water reactors, prismatic and pebble-bed liquid-salt cooled reactors, molten-salt reactors, sodium and lead-alloy cooled fast reactors, breed-and-burn reactors, heat-pipe reactors as well as fusion-fission hybrid reactors and accelerator driven nuclear reactors. His research is documented in over 400 refereed publications, over 200 non-refereed publications, 5 book chapters, and a number of patents.

Introduction

From the beginning of the Universe through to the present day, nuclear energy, nuclear reactions, and nuclear radiations have played major roles in the evolution and shaping of our universe and planet Earth. All the chemical elements we find on Earth were produced by nuclear processes in the Universe. Planet Earth is continuously exposed to nuclear radiation from primordial radioactive isotopes produced in cosmological processes that followed the Big Bang. A number of primordial radioactive isotopes are still among the Earth's constituents, including thorium ^{232}Th , the uranium isotopes ^{235}U and ^{238}U as well as potassium ^{40}K . The spontaneous radioactive decay of the nuclides of these isotopes releases nuclear energy that provides a major contribution to the heat balance of planet Earth. The internal heat source is responsible for keeping the outer core of the Earth in a molten magma state and played a major role in the geologic evolution of the Earth's continents and oceans. The primordial radiation and Earth's heat source may have also contributed to the creation as well as evolution of life on Earth. Since its birth, the Earth has been also constantly bombarded by galactic cosmic nuclear radiation, which primarily consists of protons (hydrogen nuclei) and alpha particles (helium nuclei). Hence, mankind as well as any organism on Earth, were and are being continuously exposed to background nuclear radiation throughout their evolution. The background radiation level as well as the radioactive heat source due to the decay of the primordial radioactive isotopes were significantly higher at the time of Earth formation and are slowly decreasing with time.

It is only within the last hundred and twenty years or so that mankind discovered the structure of the atom and its nucleus and learned how to harness the enormous energy potential contained within the nucleus as well as the different types of radiation nuclei and atoms can emit. Nuclear radiation was discovered in 1896, when Henry Becquerel and Marie Curie discovered that salts of uranium emitted radiation that could be detected with photographic plates. In the 125 years since this discovery, mankind deciphered the structure of the atom and its nucleus, learned how to produce artificial radioactive isotopes (Irène Joliot-Curie and Frédéric Joliot in 1934), discovered how to fission certain heavy isotopes (Otto Hahn, Fritz Strassmann, Lise Meitner and Robert Frisch, 1938/39) and learned how to establish a fission chain reaction (Leo Szilard, Enrico Fermi et al., 1942) and developed numerous applications of nuclear radiation and nuclear energy. The feasibility of releasing nuclear energy by fusing nuclei of light isotopes was postulated already in 1920 (Arthur Eddington) who speculated that such nuclear reactions provide the enormous energy released in the sun and stars. Although research of harnessing nuclear fusion for controlled generation of nuclear energy is being pursued since the late 1940s, mankind has not yet succeeded in producing sufficiently more energy from fusion reactions than the energy invested in inducing these reactions. Additional information on the history and fundamentals of harnessing nuclear energy can be found in (Norman, 2021).

Encyclopedia scope

The Encyclopedia of Nuclear Energy (The Encyclopedia) provides a comprehensive authoritative coverage of a wide range of topics related to the generation, utilization and safe handling of nuclear energy, nuclear radiation and associated technologies, for the benefit of mankind and planet Earth. It covers past developments, the present status, and research and development of advanced innovative technologies that may enable improvements in the generation and utilization of nuclear energy (including nuclear radiation). The Encyclopedia consists of 272 thematic articles written by experts and arranged in 13 Sections; each Section covers the subject area identified in Table 1.

The fundamental concept of this encyclopedia is to provide all this vast and very diversified information in convenient to read cross-referenced articles within a single publication. Each article provides an effective solid foundation of its topic and references for readers interested in deeper exploration of the subject matter.

Table 1 Encyclopedia sections, number of articles per section and the section editors.

Sec. #	Section title (# of articles)	Section editor	Section editor affiliation
1	Fundamentals and history of development of nuclear energy (17)	Eric B. Norman	Professor in the Graduate School, Nuclear Engineering Department, University of California at Berkeley
2	Commercial nuclear power reactors and their design (22)	Russell E. Stachowski	Chief Consulting Engineer, Global Nuclear Fuel
3	Advanced nuclear reactor concepts under R&D (28)	Alexander Stanculescu	Retired Generation Four International Forum Technical Director; Retired Idaho National Laboratory Division Director
4	Safety, regulation, and decommissioning of commercial nuclear power reactors (24)	Joy L. Rempe	Rempe and Associates, LLC
5	Fuel cycle front-end: from mining through utilization (17)	Douglas C. Crawford	Director, Transient Reactor Test Facility, Idaho National Laboratory.
		Colby B. Jensen	National Technical Lead for Fuel Safety Research, Idaho National Laboratory
6	Fuel Cycle back-end: from recycling to deep geological disposal (19)	Christophe Poinssot	Deputy General Director (CEO) and Scientific Director of the French Geological Survey (BRGM) ^a
7	Radiation protection (21)	Laurence Miller	Professor Emeritus, Department of Nuclear Engineering, the University of Tennessee
8	Non-electric applications of nuclear energy (15)	Shannon M. Bragg-Sittou	Lead for Integrated Energy Systems, Idaho National Laboratory ^b
9	Nuclear power for space (16)	David I. Poston	Chief Reactor Designer, Los Alamos National Laboratory
10	Research reactors (23)	Sean O'Kelly	Associate Laboratory Director, Idaho National Laboratory. Chair of IAEA Technical Working Group on Research Reactors
11	Medical, industrial and agricultural applications of nuclear technology (26)	Alan E. Waltar	Retired Professor and Head, Department of Nuclear Engineering, Texas A&M University, College Station
12	Nuclear fusion R&D (26)	David J. Campbell	Munich, Germany. Former Director for Science and Operations, ITER Organization
13	Social issues of nuclear energy (18)	Andrew C. Kadak	Kadak Associates, Inc. Former Professor of the Practice Massachusetts Institute of Technology

^aAlso: Prof. of Nuclear Chemistry at the National Institute of Nuclear Science and technology (INSTN).

^balso National Technical Director for the DOE-NE Integrated Energy Systems program.

Intended readership

The articles are written at a level that users, with a bachelor degree in engineering, scientific and medical disciplines, especially in nuclear engineering, will find understandable and helpful. The Encyclopedia is intended to be an invaluable resource for students and will make an important contribution to the preservation of the vast amount of knowhow developed since the dawn of the nuclear era in the nuclear energy related fields and to its transfer to the new generation.

The Encyclopedia will also be very useful to industry and academia researchers and practitioners in the many scientific and engineering fields related to the generation and use of nuclear energy, including nuclear radiation. It will enable researchers and practitioners to refresh their memory in their field of specialization or expand their knowhow on less familiar subject areas.

The Encyclopedia will also be useful to members of the public with education in engineering or sciences who are interested in learning about specific nuclear energy or nuclear radiation related topics without having to struggle with textbooks or journal articles.

On the need for this Encyclopedia

The publication of this Encyclopedia is very timely for a number of reasons, including the following:

- Nuclear energy can play a very important role in drastically reducing the amount of fossil fuels burned for generation of electricity and, hence, the amount of greenhouse gas (GHG; primarily CO₂) emissions while, at the same time, making more electricity available for developing countries and for supporting the expected growth in the world population. Moreover, nuclear energy can make an important contribution to drastically reducing the amount of GHG emission from the transportation, industrial, residential and agricultural sectors of the economy. Hence, nuclear energy can make a vital contribution to meet the goal set by the 2015 Paris Agreement on climate change and ratified by many nations—to limit global warming to well below 2, preferably to 1.5 degrees Celsius, compared to pre-industrial levels. This point is elaborated upon below in the section: “On the Importance of Nuclear Energy in Avoiding Climate Change Catastrophe”. The state of the art in nuclear energy generation is covered in (Stachowski, 2021; Crawford, 2021).

- The Generation IV (GEN-IV) International Forum (GIF) was created in 2001 as a co-operative international endeavor of research, development, demonstration and deployment of advanced fourth generation innovative nuclear reactors that, hopefully, will be available for commercial deployment by 2030. The objectives of the innovative GEN-IV nuclear energy systems include improved sustainability, economics, safety and reliability, as well as proliferation resistance and physical protection. This encyclopedia provides an update on the state of the GEN-IV R&D efforts and explains the benefits the innovative GEN-IV reactors may provide. The Encyclopedia also describes (Stanculescu, 2021) the advanced nuclear fuel cycles that offer highly improved resource utilization, greatly reduced nuclear waste, and reduced proliferation risks.
- Over the past decade or so, there has been a surge in the number of private companies, mostly supported by venture capital, that are developing advanced innovative Small Modular Reactors (SMRs); reactors designed to generate between 10 to 300 MW of electricity per unit (Stanculescu, 2021). The SMRs offer a new paradigm in the generation and delivery of nuclear power; they promise to improve all aspects of design, engineering, construction and operation of commercial nuclear power plants, including enhanced safety performance, better economic affordability, and reduced financial risk. The components (modules) of SMRs are to be of a standard design, shop fabricated in assembly lines subjected to high quality control, and then transported as complete modules to the power plant site for rapid installation. The SMRs also offer flexible power generation for a wider range of users and applications—central power stations can consist of multiple units installed at a rate that best matches the growth in power demand; alternatively, a single SMR unit can be installed in the vicinity of the power customer using a so-called distributed (localized) power grid. It is even being proposed that the hundreds of shuttered coal power plant sites could be repurposed for SMRs. This encyclopedia describes (Stanculescu, 2021) a sample of the SMRs under development and explains the incentives for their development and the benefits they offer. The Encyclopedia also describes the motivation for, and examples of, so called “microreactors”—reactors producing an electrical power of less than 10 MW. Such reactors are primarily intended for deployment in remote areas which are not connected to the grid and to which the transport of fossil fuel is very expensive, as well as to provide reliable power to sensitive installations even in case of failure of the central power grid.
- The very ambitious space explorations being planned by leading industrial countries cannot succeed without nuclear energy. Space Fission Power (SFP) systems offer the potential to enable truly ambitious exploration of outer space, and ultimately a permanent human presence in space. Most of the benefits of SFP is tied to the very high amount of energy that can be extracted per unit weight of fissile material, which can allow high powers and/or long lifetime at a relatively low mass. SFP systems also offer great flexibility in terms of being able to operate in diverse environments, including environments with no or limited solar radiation, and the ability to provide abundant electrical power and heat from kilowatts to megawatts. Applications of SFP include propulsion and/or power for spaceships, electricity and heat for exploration rovers for landing on Mars (other planets and moons) or for human colonies on the Moon or Mars. This encyclopedia describes (Poston, 2021; Bennett, 2021) the many benefits nuclear energy offers to space exploration and the many challenges that need to be overcome.
- Controlled thermonuclear fusion is the focus of major international research programs that aim to demonstrate the scientific and technological feasibility of large-scale generation of nuclear energy by the fusion of light atomic nuclei. The widely distributed fusion fuel resources together with the favorable anticipated safety and environmental characteristics of future fusion power plants provide a significant motivation for the continued development of the challenging science and technology towards the exploitation of fusion energy for the benefit of mankind. In addition to the description of the fundamental elements of the fusion process and of the principal approaches to the controlled and sustained generation of fusion energy being pursued, this Encyclopedia presents the state-of-the-art for fusion research and development and the progress towards commercial fusion energy generation (Campbell, 2021). The advantages and challenges of nuclear fusion as an energy source are summarized.
- This encyclopedia also describes the many ways nuclear radiation can be harnessed to provide enormous benefits in the fields of medicine, agriculture, modern industry, environmental protection, and public safety (Waltar, 2021). Described in the Encyclopedia are more than a dozen unique properties of radiation technology that allow for these benefits to be achieved. Even though enormous and widespread, the benefits to society from these technologies are largely unknown and unappreciated. The global markets for these technologies exceed USA \$500 billion annually and are growing rapidly.
- Also provided in this Encyclopedia is information on dozens of research reactors (O’Kelly, 2021) that are operating or under construction around the world and provide unique research capability for scientists pursuing advanced research in physics, chemistry, biology, material and other sciences. Another invaluable utilization of research reactors is the production of special radioactive isotopes for numerous applications in medical, industrial and agricultural applications, and scientific research. Some research reactors are also used for demonstrating the performance of evolutionary as well as advanced nuclear fuels and of advanced nuclear power reactor components.
- Public perception of nuclear energy varies from country to country. It tends to be most negative in wealthy democracies like Germany, Australia, and Japan. Contributing to the negative perception is a fear of reactor accidents, a fear of nuclear radiation, a fear of long-lived radioactive waste, and a fear of the nuclear technology misuse for weapons proliferation. The encyclopedia addresses these concerns and provides authoritative objective information that, hopefully, will contribute to dispelling the public misconceptions (Kadak, 2021).
- The Encyclopedia describes measures implemented to ensure the health and safety of the public from nuclear power (Rempe, 2021). These measures evolved as new lessons were learned from operating experience and unplanned events, in particular events with core damage and radionuclide release (including in Three Mile Island, Chernobyl, and Fukushima). Clearly, the

experience gained from the design, evaluation, operation, decommissioning, and regulation of nuclear power plants has led to significant safety improvements. Future advanced reactor designs are expected to incorporate innovative inherent safety features (Stanculescu, 2021).

- The encyclopedia provides a detailed description of the biological effects of nuclear radiation, of how we reliably measure radiation levels and ensure that they do not exceed the permissible levels (Miller, 2021). The Encyclopedia describes the theory and practice of radiation protection that provide the basis for regulatory requirements that are essential for the safe and beneficial use of the many advanced technologies that involve exposure to nuclear radiation. The Encyclopedia explains that everyone is exposed to natural background radiation on a daily basis; that radiation is routinely in use for diagnostics of health conditions, such as for dental and medical X-rays, and that this is the largest source of radiation exposure for almost all human population in developed countries and that the benefits from these practices far exceed their risk. The regulatory permissible level of nuclear radiation is harmless much like a moderate exposure to sunshine is harmless (and may even be beneficial, whereas over-exposure can cause sunburns). In other words, the regulatory limits of doses induced by exposure to nuclear radiation are already substantively protective, and there is no evidence of health improvements by reducing the doses below these limits. Insisting to reduce radiation exposure to as low as possible below the regulatory limits may result in harm.
- Also provided in this Encyclopedia is detailed information about the nuclear waste and how it can be disposed of safely (Poinssot, 2021; Kadak, 2021). Using advanced fuel cycles (Stanculescu, 2021; Poinssot, 2021) the amount and activity of the long-lived nuclear waste can be reduced to few percent of the amount that needs to be disposed of per unit of energy generated using the contemporary “once-through” fuel cycle.

On the importance of nuclear energy in avoiding climate change catastrophe

The world’s population is expected to grow from current ~6.7 billion people to over 9 billion by 2050. As recognized in the United Nations Resolution 70/1 “Transforming our world: the 2030 Agenda for Sustainable Development” (Stanculescu, 2021; United Nations, 2015), providing “universal access to affordable, reliable and sustainable energy” and in particular to reliable electrical energy, is central to human development, social stability and even world peace. Currently, about 2.8 billion people are still lacking modern energy services (International Energy Agency, 2017), and more than one billion do not have access to electricity. Not only the growth of worldwide population, but also the economic growth in developing countries will lead to a continuing increase in the demand for energy.

The tremendous increase in energy generation required for the benefit of the global population has to be accomplished while reducing the rate of GHG (primarily CO₂) emission. Already, “human activities are estimated to have caused approximately 1.0 °C of global warming above pre-industrial levels” according to the Intergovernmental Panel on Climate Change (IPCC, 2018). In order to limit the global temperature increase to around 1.5 °C, total CO₂ emissions need to be reduced to net zero by around 2050.

Germany, for example, had decided to achieve this goal by installing renewable energy generators made of solar photovoltaic panels and wind turbines. Germany also decided to close down its nuclear power plants. As a result, according to Goldstein et al. (2019), “Germany, which went all-in for renewables, has seen little reduction in carbon emissions, and, according to our calculations, at Germany’s rate of adding clean energy relative to gross domestic product, it would take the world more than a century to decarbonize, even if the country wasn’t also retiring nuclear plants early. A few lucky countries with abundant hydroelectricity, like Norway and New Zealand, have decarbonized their electric grids, but their success cannot be scaled up elsewhere; the world’s best hydro sites are already dammed.”

Goldstein et al. (2019) are also saying “we actually have proven models for rapid decarbonization with economic and energy growth: France and Sweden. They decarbonized their grids decades ago and now emit less than a tenth of the world average of carbon dioxide per kilowatt-hour. They remain among the world’s most pleasant places to live and enjoy much cheaper electricity than Germany to boot. They did this with nuclear power. And they did it fast, taking advantage of nuclear power’s intense concentration of energy per unit weight of fuel. France replaced almost all of its fossil-fueled electricity with nuclear power nationwide in just 15 years; Sweden, in about 20 years. In fact, most of the fastest additions of clean electricity historically are countries rolling out nuclear power.”

In the words of World Nuclear Association Director General Agneta Rising in 2019 (Bisconti, 2021): “The 445 nuclear reactors in 30 countries are the low-carbon backbone of electricity systems, operating in the background, day in day out, often out of sight and out of mind, capable of generating an immense amount of clean power. They are the silent giants upon which we rely today.” Table 2 lists the fraction of electricity generated during 2018 in selected countries and globally from energy sources that do not emit greenhouse gases (Pioro et al., 2021). According to Poinssot and Bourg (2021), nuclear energy is within the top three of the most environmental-friendly energy sources; in the same range as hydropower and wind-power. Measured by CO₂ emissions, nuclear energy is even the most environmentally friendly energy source.

It is being suggested (Conca, 2021) that recent research has revealed the potential for extracting practically unlimited supplies of uranium from the oceans at a cost that may come close to that of land mining. If successful, this may make fission nuclear energy practically as renewable as wind and solar (Conca, 2021).

It is not sufficient to decarbonize the electricity generation sector. In the U.S., for example, 33% of CO₂ emissions are attributed to energy generated to support the electricity sector but an additional 36% of emissions result from transportation and 19% result

Table 2 Fraction of electricity generated by clean energy technologies in selected countries.

Country	Nuclear	Renewable	HYDRO
France	72	3	11
Ukraine	53.5	0.7	4.2
Sweden	41	10.2	39
UK	25	25	-
Korea	23.4	0	1.3
Russia	19.0	0	17
USA	19.7	10.9	6.6
Germany	11.6	22.2	-
World	10.2	6.6	16.3

from industrial processes (Bragg-Sitton and Boardman, 2021). There will be no global environmental benefits from switching transportation to use all electric vehicles if the electricity used for charging the batteries is generated in fossil fuel power plants (without sequestration of the CO₂ these plants emit). The realization of the above-mentioned facts is recently leading to a paradigm shift in the approach to the use of nuclear energy that is likely to bring about a restructuring in the entire energy market.

**Fig. 1** Illustrative examples of the near-term integration of existing LWRs with various industry applications (Bragg-Sitton and Boardman, 2021).

Fig. 2 Conceptualized coordination of energy generation sources and demand to maximize flexibility and economic performance while ensuring grid reliability and resilience.

Most energy experts around the world are advocating the development of a portfolio of low-carbon multi-energy technologies including, in addition to hydro-power plants (with very limited potential for expansion in capacity) and the currently favored “renewable” electricity generators, nuclear power plants. Because the power output of the renewable generators greatly fluctuates over the day and over the year, these generators need to be supplemented by effective energy storage devices that significantly add to the cost of energy.

Nuclear power plants, on the other hand, can generate power at a constant rate throughout the day and the year (excluding a shutdown period of ~1 month for refueling and maintenance once every 18–24 months), practically independent of weather conditions, while requiring a smaller land area per unit energy generated relative to the area required by renewable energy generators.

Moreover, nuclear energy can be generated in the form of high temperature heat (Stanculescu, 2021; Bragg-Sitton and Boardman, 2021) that is the most economical form of energy to store and to use as a backup for the intermittent nature of the renewable energy generators. Therefore, a suitable mix of nuclear and renewables is likely to be the optimal strategy for carbon-free energy generation.

Fig. 1 (Bragg-Sitton and Boardman, 2021) is a simplified illustration of the evolving perception of integrated energy systems using contemporary nuclear power reactors (primarily Light Water Reactors, LWR) in combination with solar and wind renewable energy generators to provide electricity and heat energy for transportation and many industries including non-grid energy users.

Fig. 2 (Bragg-Sitton et al., 2021) is a simplified conceptual perception of the proposed transition away from the use of contemporary large central nuclear power plants from their traditional electricity-only production mode to their exploitation for the provision of a variety of outputs. Future energy systems that seek to maximize energy utilization, generator profitability, and grid reliability and resilience must necessarily consider all available carbon-free energy sources, using each available resource in a way that maximizes its benefits while minimizing less-desirable attributes. The future energy systems should include advanced nuclear reactors including Gen-IV reactors, SMRs and even microreactors and should use distributed in addition to centralized electricity grids.

In summary, the need to meet the objective of zero net CO₂ emission by 2050 combined with the need to greatly increase the total global energy generation rate is an enormous challenge that can be achieved only by making use of all available clean energy generation technologies including nuclear in addition to solar and wind electricity generators. At the 2021 Earth Day climate summit, U.S. president Biden called (WSJ, 2021) for slashing U.S. greenhouse gas emissions by 2030 by 50%–52% compared with the baseline year of 2005, as he seeks to put America at the forefront of world-wide efforts to combat climate change. According to WSJ (2021), meeting this objective would require dramatically reshaping key sectors of the economy, from energy to transportation to agriculture.

Concluding remarks

This Encyclopedia of Nuclear Energy provides a very comprehensive, up-to-date and authoritative information related to nuclear energy, including nuclear radiation—from the discovery of the structure of the atom and its nucleus; through the discovery of three different ways to extract energy from nuclei (fission of heavy nuclei, fusion of light nuclei and radioactive decay); through the state-of-art of the nuclear industry for energy generation and for exploitation of several nuclear technologies for medical, industrial, agricultural and other applications; to the research and development of innovative nuclear technologies that are expected to further

increase mankind benefits from nuclear energy. The reader can find in the Encyclopedia a wide range of topics ranging from the contribution of nuclear energy to the evolution of the continents and oceans of planet Earth to the enabling of very ambitious space explorations including the provision of electricity and heat to human colonies on the Moon, Mars and beyond. The Encyclopedia explains why it is essential to greatly increase the nuclear energy generation rate in order to prevent a global warming catastrophe and, at the same time, provide sufficient energy to the growing world population and to the billions of people in underdeveloped countries.

It is hoped that this Encyclopedia will make an important contribution to transferring of the huge amount of technical knowledge accumulated in the field to the young generation, will inspire students to join research and development of innovative nuclear technologies and will contribute to better understanding of the nuclear technologies, their merits and safety by the general public and policy makers. The appreciation of the enormous benefits in the fields of steady reliable clean energy generation, medicine, agriculture, modern industry, environmental protection, and public safety that mankind enjoys every day and which is described in this Encyclopedia will, hopefully, contribute to much greater public acceptance and support of enhanced utilization of nuclear energy in the mix of clean energy technologies.

Acknowledgments

The Editor-in-Chief is very thankful to the Editors of the 13 sections of this encyclopedia who worked very hard and with dedication to compose the scope of their sections, find expert authors for each of their section articles and finally review and revise these articles. Many thanks are also due to the several hundred authors of the encyclopedia articles who agreed to share their expert know-how with the readers. The support provided by the Encyclopedia Content Project Manager Natalie Lovell, by the Associate Content Project Manager, Gayathri S and their staff is highly appreciated.

CONTRIBUTORS TO VOLUME 1

Eric Abonneau

Commissariat à l'Energie Atomique et aux Energies Alternatives, Paris, France

Tim Abram

Manchester University, Manchester, United Kingdom

Alessandro Alemberti

Ansaldo Nucleare SpA, Genova, Italy

M Arcaro

Principal Engineer, GE-Hitachi Nuclear Energy-Systems Engineering, Wilmington, NC, United States

Benjamin R Betzler

Oak Ridge National Laboratory, Oak Ridge, TN, United States

Jeffery A Brown

Westinghouse Electric Company, Pittsburgh, PA, United States

Nicholas R Brown

Department of Nuclear Engineering, University of Tennessee, Knoxville, TN, United States

Mike W Davies

Jacobs Clean Energy Limited, Knutsford, Cheshire, United Kingdom

Daniel E DiGregorio

School of Science and Technology, National University of San Martín, Buenos Aires, Argentina; and Constituent Atomic Center, National Atomic Energy Commission, Buenos Aires, Argentina

RB Duffey

Idaho Falls, ID, United States

Lyndon Edwards

Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia

Carlo Fiorina

Laboratory for Reactor Physics and System Behaviour, EPFL, Lausanne, Switzerland

Massimiliano Fratoni

Nuclear Engineering Department, University of California, Berkeley, CA, United States

Michael A Fütterer

European Commission, Joint Research Centre, Petten, The Netherlands

Alejandro Garcia

Department of Physics, University of Washington, Seattle, WA, United States

J Gehin

Idaho National Laboratory, Idaho Falls, ID, United States

E Greenspan

Department of Nuclear Engineering, University of California, Berkeley, CA, United States

W Halsey

Lawrence Livermore National Laboratory, Livermore, CA, United States

David A Hamon

GE-Hitachi Nuclear Energy, San Jose, CA, United States

Ke Han

School of Physics and Astronomy, Shanghai Jiao Tong University, Shanghai, China

Branislav Hatala

VUJE, A.s., Trnava, Slovak Republic

F Heidet

Argonne National Laboratory, Lemont, IL, United States

Pavel Hejzlar

TerraPower, LLC, Bellevue, WA, United States

Yanping Huang

Nuclear Power Institute of China, Chengdu, China

Victor V Ignatiev

NRC-Kurchatov Institute, Moscow, Russian Federation

Minwhan Kim
Korea Atomic Energy Research Institute, Daejeon, South Korea

PL Kirillov
State Scientific Centre of the Russian Federation, Al
Leypunsky Institute of Physics and Power Engineering
(IPPE), Obninsk, Russia

Karen Vierow Kirkland
Department of Nuclear Engineering, Texas A&M
University, College Station, TX, United States

Jennifer L Klay
California Polytechnic State University, San Luis
Obispo, CA, United States

Kevin J Kramer
TerraPower, LLC, Bellevue, WA, United States

Kenneth S Krane
Department of Physics, Oregon State University,
Corvallis, OR, United States

Jiri Krepel
Paul Scherrer Institut, Villigen, Switzerland; and Paul
Scherrer Institute, Villigen, Switzerland

Laurence Kim-Hung Leung
Canadian Nuclear Laboratories, Chalk River, ON,
Canada

Fu Li
INET, Tsinghua University, Beijing, China

Evzen Losa
Department of Nuclear Reactors, Czech Technical
University, Prague, Czechia

G Ivan Maldonado
Department of Nuclear Engineering, University of
Tennessee, Knoxville, TN, United States

RP Martin
Technical Consultant, BWX Technologies, Inc.,
Lynchburg, VA, United States

Reina Maruyama
Department of Physics, Yale University, New Haven,
CT, United States

Edward C Morse
University of California, Berkeley, CA, United States

Ondrej Muransky
Australian Nuclear Science and Technology
Organisation, Lucas Heights, Australia

Jim Napolitano
Temple University, Philadelphia, PA,
United States

Eleodor Nichita
Faculty of Energy Systems and Nuclear Science, Ontario
Tech University, Oshawa, ON, Canada

Eric B Norman
Department of Nuclear Engineering, University of
California, Berkeley, CA, United States

I Pioro
University of Ontario Institute of Technology, Oshawa,
ON, Canada

R Pioro
Faculty of Physics, Lomonosov Moscow State University,
Moscow, Russia

Manuel A Pouchon
Paul Scherrer Institut, Villigen, Switzerland

E Previtali
Department of Physics, University of Milano-Bicocca,
Milan, Italy

Staffan Qvist
Qvist Consulting Limited, London, United Kingdom

B Cameron Reed
Department of Physics (Emeritus), Alma College, Alma,
MI, United States

Frederik Reitsma
Ultra Safe Nuclear Corporation (USNC-Europe),
Olette, France

Geoffrey S Rothwell
Department of Economics (Retired), Stanford
University, Stanford, CA, United States; and Jean
Michard Pélissier, Antibes, France

Ramesh Sathankar
Canadian Nuclear Laboratories, Chalk River, ON,
Canada

Hiroyuki Sato
Japan Atomic Energy Agency, Ibaraki, Japan

Hiroshi Sekimoto
Tokyo Institute of Technology, Tokyo, Japan

Seok Bin Seo
Department of Nuclear Engineering, University of
Tennessee, Knoxville, TN, United States

Phil Sharpe
Studsvik Scandpower, Inc., Wilmington, NC, United
States

Jennifer Shusterman
Department of Chemistry, Hunter College of the City
University of New York, New York, NY, United States;
and Graduate Center of the City University of New
York, New York, NY, United States

Eugene Shwageraus
*Department of Engineering, University of Cambridge,
Cambridge, United Kingdom*

Craig F Smith
*Department of Physics, Naval Postgraduate School,
Monterey, CA, United States*

Russell E Stachowski
Global Nuclear Fuel, Wilmington, NC, United States

Alexander Stanculescu
*Idaho National Laboratory, Nuclear Systems Design and
Analysis Division, Idaho Falls, ID, United States; and
Generation IV International Forum (GIF)*

Gerhard Strydom
*Idaho National Laboratory, Idaho Falls, ID, United
States*

Andrew E Stuchbery
*Department of Nuclear Physics, The Australian National
University, Canberra, ACT, Australia*

M Hadid Subki
*Nuclear Power Technology Professional, Vienna,
Austria; and International Atomic Energy Agency,
Vienna, Austria*

T Taiwo
Argonne National Laboratory, Lemont, IL, United States

M Todosow
*Brookhaven National Laboratory, Upton, NY, United
States*

Pavel V Tsvetkov
*Department of Nuclear Engineering, Texas A&M
University, College Station, TX, United States*

Belle R Upadhyaya
*Department of Nuclear Engineering, University of
Tennessee, Knoxville, TN, United States*

Janne Wallenius
*Division of Nuclear Engineering, KTH, Stockholm,
Sweden*

William Walters
*Ken and Mary Alice Lindquist Department of Nuclear
Engineering, Pennsylvania State University, State
College, PA, United States*

David K Wehe
*Department of Nuclear Engineering and Radiological
Sciences, University of Michigan, Ann Arbor, MI,
United States*

Fred E Wietfeldt
*Department of Physics and Engineering Physics, Tulane
University, New Orleans, LA, United States*

R Wigeland
*Idaho National Laboratory, Idaho Falls, ID, United
States*

Richard T Wood
*Department of Nuclear Engineering, University of
Tennessee, Knoxville, TN, United States*

Metin Yetisir
*Canadian Nuclear Laboratories, Chalk River, ON,
Canada*

Michael Y Young
*Westinghouse Electric Company, Pittsburgh, PA, United
States*

CONTENTS OF ALL VOLUMES

<i>Editorial Board</i>	<i>v</i>
<i>Editor-In-Chief</i>	<i>vii</i>
<i>Introduction to the Encyclopedia of Nuclear Energy</i>	<i>ix</i>
<i>Contributors to Volume 1</i>	<i>xvii</i>

VOLUME 1

Fundamentals and History of Development of Nuclear Energy

Introduction to Fundamentals and History of Development of Nuclear Energy <i>Eric B Norman</i>	1
What Is the Universe Made of? <i>Alejandro Garcia</i>	3
Discovery of Radioactivity <i>Daniel E DiGregorio</i>	9
Discovery of the Quantum Structure of Atoms and Their Nuclei <i>Kenneth S Krane</i>	19
Origins of Nuclear Energy <i>Jim Napolitano</i>	29
Radioactive Decay <i>E Previtali</i>	35
Nuclear Fission I <i>Jennifer L Klay</i>	45
Nuclear Fission II <i>Andrew E Stuchbery</i>	53
Fissile and Fertile Fuels <i>Jennifer Shusterman</i>	66
Manhattan Project <i>B Cameron Reed</i>	78

Nuclear Fusion <i>Edward C Morse</i>	92
Atomic and Hydrogen Bombs <i>Jim Napolitano</i>	101
Phenomenology of Neutron Interactions <i>Fred E Wietfeldt</i>	107
Phenomenology of Gamma Ray and Charged Particles Interactions <i>Reina Maruyama</i>	117
Radiation Sources <i>David K Wehe</i>	125
Experimental Tools I: Radiation Detectors <i>Ke Han</i>	133
Experimental Tools II: Particle Accelerators <i>Alejandro Garcia</i>	146
Commercial Nuclear Power Reactors and their Design	
Commercial Nuclear Power Reactors and Their Design—Introduction <i>Russell E Stachowski</i>	153
History of PWR and BWR Development <i>Jeffery A Brown and G Ivan Maldonado</i>	157
Physics of the Fission Chain Reaction in Thermal and Fast Reactors <i>Pavel V Tsvetkov and Russell E Stachowski</i>	172
Principles of Design and Operation of Nuclear Power Reactors <i>David A Hamon</i>	187
Pressurized Water Reactors <i>Jeffery A Brown</i>	196
Boiling Water Reactors <i>David A Hamon</i>	214
Heavy-Water Reactors <i>Eleodor Nichita</i>	236
Commercial Nuclear Power Plant Statistics <i>David A Hamon</i>	252
Pros and Cons of Commercial Reactor Designs Part 1: Current Status of Electricity Generation in the World and Selected Countries <i>I Pioro, RB Duffey, PL Kirillov, and R Pioro</i>	263
Pros and Cons of Commercial Reactor Designs: Part 2—Current Status and Future Trends in the World Nuclear-Power Industry and Technical Considerations of Nuclear-Power Reactors <i>I Pioro, RB Duffey, PL Kirillov, and R Pioro</i>	288
Economics of Nuclear Energy <i>Geoffrey S Rothwell</i>	304

Economic Challenges of Nuclear Energy <i>Geoffrey S Rothwell</i>	317
Fuel Rod, Fuel Assembly, and Reactivity Control Assembly Design <i>Michael Y Young</i>	327
Heat Transfer Systems <i>Karen Vierow Kirkland</i>	345
Instrumentation and Control Systems of Nuclear Power Plants <i>Belle R Upadhyaya and Richard T Wood</i>	373
Reactor Operations <i>Michael Y Young</i>	393
Operational Analysis Methods <i>William Walters</i>	405
Transient Analysis Methods <i>RP Martin</i>	422
Containment <i>Phil Sharpe</i>	439
Design of the Balance of Plant <i>M Arcaro</i>	446
Safety of Nuclear Reactors <i>Nicholas R Brown and Seok Bin Seo</i>	456
Management of the Nuclear Waste – Via Disposition or Transmutation <i>Pavel V Tsvetkov</i>	465
Advanced Nuclear Reactor Concepts Under R&D	
Worldwide Status of Advanced Reactors (GEN IV) Research and Technology Development <i>Alexander Stanculescu</i>	478
Sodium-Cooled Fast Reactors <i>F Heidet</i>	490
The High Temperature Gas-Cooled Reactor <i>Michael A Fütterer, Gerhard Strydom, Hiroyuki Sato, Fu Li, Eric Abonneau, Tim Abram, Mike W Davies, Minwhan Kim, Lyndon Edwards, Ondrej Muransky, Manuel A Pouchon, and Metin Yetisir</i>	512
Lead Cooled Fast Reactors <i>Alessandro Alemberti</i>	523
Gas Cooled Fast Reactor System (GFR) <i>Branislav Hatala</i>	545
Molten Salt Reactors <i>Victor V Ignatiev</i>	553
Super-Critical Water-Cooled Reactor (SCWR) <i>Yanping Huang, Jinguang Zang, and Laurence Kim-Hung Leung</i>	569
Advanced Light Water-Cooled Reactor Concepts <i>Eugene Shwageraus</i>	582

Fluoride-Salt-Cooled High-Temperature Reactors <i>Massimiliano Fratoni</i>	602
Introduction to Breed and Burn Reactors <i>Staffan Qvist</i>	609
Molten Chloride Fast Reactors (MCFRs) <i>Jiri Krepel and Kevin J Kramer</i>	625
Traveling Wave Reactor (TWR®) <i>Pavel Hejzlar</i>	643
CANDLE Reactor Concept <i>Hiroshi Sekimoto</i>	657
A Seed-Driven Breed-and-Burn Blanket Core Concept <i>E Greenspan</i>	673
Worldwide Status of Small Reactors Research and Technology Development <i>Frederik Reitsma and M Hadid Subki</i>	685
Water Cooled Small Modular Reactors (Integral PWR and BWR) <i>M Hadid Subki</i>	694
Floating Nuclear Power Plants With Small Modular Reactors <i>M Hadid Subki</i>	711
Pebble Bed Gas Cooled Reactors <i>Frederik Reitsma</i>	721
Heavy Liquid Metal (HLM) Cooled Fast Small Modular Reactors <i>Craig F Smith</i>	732
Micro-Reactors <i>Janne Wallenius</i>	749
Light Water Reactors (LWR) Fuel Cycle Options <i>Eugene Shwageraus</i>	757
Advanced Fuel Cycles Identification and Evaluation <i>R Wigeland, T Taiwo, M Todosow, W Halsey, and J Gehin</i>	771
Self-Sustaining Breeding in Advanced Reactors: Characterization of Natural Resources <i>Jiri Krepel</i>	786
Self-Sustaining Breeding in Advanced Reactors: Characterization of Selected Reactors <i>Jiri Krepel and Evzen Losa</i>	801
Self-Sustaining Breeding in Advanced Reactors: Comparison of Fuel Cycle Performance <i>Jiri Krepel</i>	820
Advanced Modeling and Simulation Methods <i>Carlo Fiorina</i>	837
Additive Manufacturing in the Nuclear Reactor Industry <i>Benjamin R Betzler</i>	851
New Reactor Concepts Deployment Challenges and Opportunities <i>Ramesh Sadhankar</i>	864

VOLUME 2

Safety, Licensing and Decommissioning of Power Reactors

Safety, Regulation, and Decommissioning of Commercial Nuclear Power Reactors—Introduction <i>Joy L Rempe</i>	1
Safety Lessons From Two Events Without Core Damage <i>Joy L Rempe</i>	6
The Three Mile Island Unit 2 Accident <i>Gordon R Skillman and Joy L Rempe</i>	17
The Chernobyl Nuclear Power Plant Unit-4 Accident <i>Alexander R Sich</i>	30
The Events at Fukushima Daiichi <i>Shinya Mizokami and Joy L Rempe</i>	53
Ensuring Safety by Design and Evaluation <i>Joy L Rempe</i>	67
Reactor Protection System <i>Robert Lutz and Bill Williamson</i>	76
Engineered Safety Features <i>Robert Lutz and Bill Williamson</i>	88
Instrumentation and Control <i>Robert Lutz and Bill Williamson</i>	99
Guidance for Operating Within Design Basis Conditions <i>Robert Lutz and Bill Williamson</i>	108
Beyond Design Basis Event Considerations <i>Robert Lutz and Bill Williamson</i>	115
Safety Evaluations <i>RO Gauntt</i>	126
Overview of Nuclear Regulation and Regulatory Framework <i>Joy L Rempe and Laurence G Williams</i>	139
U.S. Regulation and Licensing—Historical Perspective <i>Dennis C Bley and Marty Malsch</i>	150
U.S. Regulations for Commercial Nuclear Power Plants <i>Dennis C Bley and Marty Malsch</i>	163
U.S. Options for Licensing a New Commercial Power Plant <i>Harold B Ray</i>	168
Regulation of Two U.S. Non-LWRs—Lessons Learned <i>Joy L Rempe</i>	175
Overview of International Nuclear Safety Regulation and Licensing <i>Laurence G Williams</i>	188
Probabilistic Risk Assessment <i>Mohammad Modarres and Inn Seock Kim</i>	207

Regulatory Applications of Risk Assessment <i>Donald A Dube</i>	218
Risk Assessment Insights and Impact <i>Karl N Fleming</i>	227
Nuclear Power Plant Decommissioning <i>Rod McCullum</i>	240
SAFSTOR Decommissioning Example (Kewaunee) <i>Rod McCullum</i>	247
DECON Decommissioning Example (Maine Yankee) <i>Rod McCullum</i>	251
The Nuclear Fuel and Fuel Cycle	
Introduction to Fuel Cycle Front End: From Mining Through Utilization <i>Douglas C Crawford</i>	255
Uranium Resources <i>Ian Hore-Lacy</i>	265
Uranium Extraction From Seawater Makes Nuclear Power Virtually Renewable <i>James L Conca</i>	277
Unconventional Uranium Resources From Phosphates <i>Nils H Haneklaus</i>	286
Uranium Conversion and Enrichment <i>Patrick Hogan</i>	292
Fuel Design and Fabrication: Pellet-Type Fuel <i>Masato Kato</i>	298
Fuel Design and Fabrication: Fast-Reactor Metal Fuels <i>Douglas L Porter and Douglas C Crawford</i>	308
Fuel Design and Fabrication: TRISO Particle Fuel <i>Grant W Helmreich and John D Hunn</i>	318
Fuel Design and Fabrication: Research Reactor Fuel <i>James I Cole, Jan-Fong Jue, and Glenn A Moore</i>	326
Nuclear Criticality Safety <i>Douglas G Bowen</i>	334
Fresh Fuel Properties: Ceramic Compounds <i>Giovanni Pastore and Aysenur Toptan</i>	343
Zr-Alloyed Metallic Fuel Properties <i>Stephen Novascone, Christopher Matthews, Albert Casagrande, Aysenur Toptan, and Adam Zabriskie</i>	356
Molten Salt Fuels: Properties, Purification, and Corrosion Control <i>Ruchi Gakhar, William C Phillips, Guoping Cao, Tae-Sic Yoo, Michael E Woods, Guy L Fredrickson, and Toni Karlsson</i>	366
Irradiation Performance: Light Water Reactor Fuels <i>Paul Cantownine and Bob Rand</i>	377

Irradiation Performance: Fast Reactor Fuels <i>Colby B Jensen and Nicolas E Woolstenhulme</i>	392
Irradiation Performance: High-Temperature Gas Reactor Fuels <i>Tyler J Gerczak</i>	407
Irradiation Performance: Research Reactor Fuels <i>James I Cole, Hakan Ozaltun, Jan-Fong Jue, Warren F Jones, Dennis D Keiser, Jr, Barry Rabin, and Mitchell K Meyer</i>	420
The Nuclear Waste and its Disposal	
Key Characteristics of Used Nuclear Fuel <i>J-P Glatz</i>	429
Fuel Storage (New Fuel/Used Fuel Pool) <i>John H Kessler</i>	441
The Chemical Basis for Separating Recycling Materials by Hydro-Processes <i>Robin Taylor</i>	450
The Chemical Basis for Separating Recycling Materials by Pyro-Processes <i>Stéphane Bourg</i>	465
The Current Industrial Mono-Recycling of U and Pu: Reprocessing Step <i>Gérald Senentz</i>	482
The Current Industrial Mono-Recycling of U and Pu: Recycling Step <i>Jean-Michel Marin</i>	494
Routes for Pu Multi-recycling <i>Bernard Boullis and Christine Chabert</i>	510
The Adaptation of Recycling Processes to Pu-Multi Recycling <i>Manuel Miguiriditchian and Robin Taylor</i>	523
Effluent Decontamination <i>V Blet</i>	534
ILW conditioning and performance <i>Samuel A Walling, Laura J Gardner, and Neil C Hyatt</i>	548
HLW Conditioning and Long-Term Performance <i>Florence Bart, Christophe Poinssot, Stéphane Gin, Sylvain Peuget, and Céline Roussel</i>	564
Spent nuclear fuel long term behavior and performance <i>Bernd Grambow</i>	577
The Concept of Geological Disposal of Highly Radioactive Nuclear Waste <i>Rodney C Ewing and Sulgiye Park</i>	588
Radionuclide Migration in the Context of High-Level Nuclear Waste Management <i>Jordi Bruno</i>	603
Main Repository Projects Worldwide <i>Soufiane Mekki</i>	616
Actinide Immobilization in Dedicated Wasteforms: An Alternative Pathway for the Long-Term Management of Existing Actinide Stockpiles <i>Lewis R Blackburn and Neil C Hyatt</i>	650

Potential Fuel Cycle Back-End for Thorium Fuel Cycle <i>Xiangzhou Cai and Zhiguang Wang</i>	663
Assessment of the Relative Environmental Footprint of Nuclear Energy and Its Fuel Cycle <i>Ch Poinssot and S Bourg</i>	675
Social Acceptability of Geologic Disposal <i>Daniel S Metlay</i>	684
Radiation Protection	
Radiation Protection – Introduction <i>Laurence Miller</i>	698
Ionizing Radiation: Discovery and Dose Quantities <i>Shaheen Azim Dewji</i>	701
Fundamentals of Health Physics <i>Shaheen Azim Dewji and Laurence Miller</i>	716
Natural and Man-Made Sources of Radiation <i>Laurence Miller, A Iulian Apostoaei, Michael Howard, and Vikram Singh</i>	744
Source Terms for Nuclear Reactors Operations, Accidents, and Waste <i>Vikram Singh and Alexander M Wheeler</i>	765
External Dosimetry <i>Ken G Veinot</i>	777
Internal Dosimetry <i>Lisa M Snapp and Keith F Eckerman</i>	790
Instrumentation and Practices for Radiological Assessments <i>Timothy J Vitkus, David A King, Nick A Altic, and Wade P Ivey</i>	803
Emergency Response <i>Craig M Marianno</i>	828
Standards to Control Radiation Exposures of Workers and the Public <i>David C. Kocher</i>	840
Risk Tradeoff Analysis <i>TW Hansen, Jr</i>	851
Computer Codes for Determining Acceptable Levels of Contamination <i>John Arnish</i>	858
Characterization and Release of Contaminated Sites <i>Timothy J Vitkus</i>	869
Radiological Control Practices <i>TW Hansen, Jr</i>	890
Radiation Shielding Methods <i>Ronald Pevey</i>	899
Shielding Against Galactic and Solar Radiation in Space <i>Lawrence Heilbronn</i>	914
Health Effects and Radiation Biology <i>Trent L Nichols and Thomas Byrne</i>	923

Estimation of Health Risks From Exposure to Ionizing Radiation <i>A Iulian Apostoaiei</i>	937
Drones for Radiological Assessment <i>Alexandra C Hackett</i>	950
An Illustrative Example of Microdosimetry—Boron Neutron Capture Therapy for Cancer <i>Trent L Nichols</i>	958
Radiation Protection: Glossary of Terms <i>Shaheen Azim Dewji, David C Kocher, and Sherry Adadi</i>	981

VOLUME 3

Non-Electric Applications of Terrestrial Nuclear Reactors

Introduction to Nonelectric Applications of Nuclear Energy <i>Shannon M Bragg-Sitton and Richard D Boardman</i>	1
District Heating and Nuclear Power <i>AE Schweikert and MR Deinert</i>	8
Nuclear Driven Water Desalination <i>Aaron S Epiney, Konor L Frick, Cristian Rabiti, Jeffrey Brown, and Shannon M Bragg-Sitton</i>	17
Nuclear-Supported Electrification of the Transportation Sector <i>Xinyu Liu, Adarsh Bafana, Pingping Sun, and Amgad Elgowainy</i>	25
Heat Pumps Driven by Zero-Carbon Electricity <i>J Stephen Herring</i>	34
Coupling Heat Storage to Base-Load Nuclear Reactors for Variable Heat, Electricity and Hydrogen <i>Charles W Forsberg</i>	40
Process Heat for Chemical Industry <i>Richard D Boardman, Michael G McKellar, Brian D Dold, Andrew W Foss, and Haydn C Bryan</i>	49
Industrial Processes for Grid Stabilization <i>Frédéric Bienvenu</i>	61
Thermochemical Hydrogen Production <i>Sellathurai(Sam) Suppiah</i>	73
High Temperature Steam Electrolysis <i>Richard D Boardman</i>	82
Synthetic Hydrocarbon Fuels From H ₂ and Captured CO ₂ <i>Lesley Snowden-Swan, Shuyun Li, Jeromy Jenks, Steven Phillips, Jalal Askander, Jamie Holladay, L Todd Knighton, and Daniel S Wendt</i>	94
Ammonia Synthesis <i>Richard D Boardman</i>	113
Hydrogen-Based Flash Ironmaking Technology (HyFIT): A Novel Green Ironmaking Technology With Low Energy Consumption <i>Hong Yong Sohn</i>	122

Calcination	131
<i>Nils H Haneklaus</i>	
Marine Propulsion	139
<i>Anil Kumar Anand and J Stephen Herring</i>	
Nuclear Power for Space and Propulsion	
Introduction to Space Nuclear Power and Propulsion	155
<i>Gary L Bennett</i>	
Radioisotope Power: Benefits and Challenges	168
<i>Gary L Bennett</i>	
Radioisotope Power: Historical Review	174
<i>Gary L Bennett</i>	
Radioisotope Power: Technology Options	191
<i>Gary L Bennett</i>	
Space Fission Power: Benefits and Challenges	201
<i>David I Poston</i>	
Space Fission Power: Historical Review	213
<i>Susan S Voss</i>	
Space Fission Power: Technology Options – Reactor Core	223
<i>David I Poston</i>	
Space Fission Power: Technology Options—Heat Transport	237
<i>David I Poston</i>	
Space Fission Power: Technology Options—Radiation Shielding	250
<i>David I Poston</i>	
Space Fission Power: Kilopower and KRUSTY	266
<i>David I Poston</i>	
Nuclear Thermal Propulsion: Benefits and Challenges	280
<i>David I Poston</i>	
The History of Nuclear Thermal Rocket Development	290
<i>Cassandra Graham</i>	
Nuclear Thermal Propulsion: Technology Options	303
<i>David I Poston</i>	
Nuclear Electric Propulsion for Rapid Transportation Within the Solar System	321
<i>Christopher Morrison</i>	
Advanced Propulsion: Pulsed, Fusion, Antimatter and Breakthrough Physics	343
<i>Steven D Howe</i>	
Space Nuclear Power Safety and Safeguards	352
<i>Patrick R McClure</i>	
Nuclear Fusion R&D	
Nuclear Fusion – Introduction and Overview	358
<i>David J Campbell</i>	

Magnetic Confinement Fusion—Principles <i>Mickey Wade</i>	369
Magnetic Confinement Fusion Concepts/Configurations <i>Ricardo MO Galvão and Gustavo P Canal</i>	383
Magnetic Confinement Fusion—Plasma Theory: Kinetic and Fluid Analysis <i>Yanick Sarazin</i>	404
Magnetic Confinement Fusion—Plasma Theory: Transport and Confinement <i>Frank Jenko</i>	419
Magnetic-Confinement Fusion—Plasma Theory: Tokamak Magnetohydrodynamic Equilibrium and Stability <i>Lang L Lao, YQ Liu, and Alan D Turnbull</i>	431
Magnetic Confinement Fusion—Plasma Theory: Energetic Particle Physics <i>NN Gorelenkov and SE Sharapov</i>	459
Magnetic Confinement Fusion—Plasma Theory: Heating and Current Drive <i>RJ Dumont</i>	479
Magnetic Confinement Fusion—Experimental Physics: Tokamak <i>Hartmut Zohm</i>	493
Magnetic Confinement Fusion—Experimental Physics: Stellarators <i>Hiroshi Yamada</i>	505
Magnetic Confinement Fusion—Experimental Physics: Reversed Field Pinches <i>M Zuin</i>	524
Magnetic Confinement Fusion—Technology: Fusion Core <i>Gianfranco Federici, Christian Bachmann, Valentina Corato, Samuel Jimenez, and Jeong-Ha You</i>	554
Magnetic Confinement Fusion Technology: “Plasma Engineering” <i>Takashi Inoue, Hiroyuki Tobari, Koji Takahashi, So Maruyama, Ryota Imazawa, and Kenichi Kurihara</i>	576
Fusion—Reactor Materials <i>A Litnovsky, I Duran, JW Coenen, Yu Gasparyan, MR Gilbert, E Hollmann, Ch Linsmeier, S Nogami, CH Skinner, and S Zinkle</i>	594
Magnetic Confinement Fusion—Reactor Blanket Technologies <i>Lorenzo Virgilio Boccaccini and Christian Day</i>	620
Magnetic Confinement Fusion—Development Facilities <i>AJH Donné, G Federici, A Ibarra, J Menard, and F Warmer</i>	635
Magnetic Confinement Fusion—Power Plant Concepts <i>David J Campbell</i>	655
Inertial Confinement Fusion – Physics Principles <i>Stefano Atzeni</i>	674
Inertial Confinement Fusion – Key Elements of Plasma Physics <i>Vladimir T Tikhonchuk</i>	686
Inertial Confinement Fusion—Experimental Physics: Laser Drive <i>Sean P Regan and E Michael Campbell</i>	713
Inertial Confinement Fusion—Experimental Physics: Heavy Ion Beam Drive <i>Peter A Seidl</i>	724

Introduction to Fundamentals and History of Development of Nuclear Energy

Eric B. Norman, Department of Nuclear Engineering, University of California, Berkeley, CA, United States

© 2021 Elsevier Inc. All rights reserved.

From the beginning in the Big Bang through to the present day, nuclear energy, nuclear reactions, and radioactive decays have played major roles in the history and evolution of our universe. However, it is only within the last 100 years or so that we have discovered the secrets of the atom and how to harness the enormous energy potential contained within the nucleus. In this section of the *Encyclopedia of Nuclear Energy*, the fundamental concepts and history of the development of nuclear science are presented by a group of internationally recognized experts in the field. The following chapters are included in this section.

Chapter 1: *What is the Universe Made Of?*, by Prof. Alejandro Garcia, University of Washington

Throughout the ages, people have wondered what our universe is made of. The early Greek notion that all things are made of four *elements*, earth, air, fire, and water, stood for 2000 years. By the 1800s, it was recognized that there are many more chemical elements which could be organized in Mendeleev's famous *periodic table*. In the early 1900s, the reality of *atoms* was experimentally confirmed. Further experiments revealed the existence of the atomic *nucleus* and its constituent *neutrons* and *protons*. Additional studies showed that neutrons and protons are actually composite objects made of different combinations of three *quarks*. This chapter describes the evolution of our understanding of what our universe is made of, and the experimental evidence supporting each step in that development is presented.

Chapter 2: *Discovery of Radioactivity*, by Prof. Daniel DiGregorio, University Nacional de San Martin

Radioactive materials have been present on Earth since its formation 4.6 billion years ago. However, it is only within the last 100 years or so that this process was identified, characterized, and eventually understood theoretically. Initial studies were conducted using naturally-occurring radioactive materials such as uranium and thorium ores. Discoveries by Becquerel, Marie and Pierre Curie, and Rutherford established that through radioactive decays, one element is transformed into another via the emission of radiation (later named alpha and beta particles). Further experimentation showed that artificial radioactivity can be produced through nuclear reactions. The history of these discoveries is described in this chapter.

Chapter 3: *Discovery of the Quantum Structure of Atoms and Their Nuclei*, by Prof. Kenneth Krane, Oregon State University

In classical physics, variables such as energy, angular momentum, and electric charge are treated as continuous quantities that can take on any value. However, in the late 1800s and early 1900s, studies of atomic structure led to the discovery that only certain discrete values of these variables actually occur. In this chapter, the experimental evidence for and the theoretical understanding of the role of *quantization* in the structure of atoms and nuclei are described.

Chapter 4: *Origins of Nuclear Energy*, by Prof. Jim Napolitano, Temple University

The mass of an atomic nucleus composed of Z protons and N neutrons is observed to be a bit less than the sum of the masses of these constituents. This difference is due to the strong nuclear force which holds the nucleus together. Through the use of Einstein's famous equation, $E = mc^2$, we can quantify the so-called nuclear binding energy which is approximately a million times greater than the binding energy of electrons in atoms. Because of the variation of the nuclear binding energy with Z and N , it is possible to release large amounts of energy through nuclear reactions such as fission and fusion and via radioactive decays. The details of how these processes can be used to produce energy are described in this chapter.

Chapter 5: *Radioactive Decay*, by Prof. Ezio Previtali, University of Milan – Bicocca

Radioactive decay is the mechanism by which unstable nuclei release energy through the emission of radiation. Over 100 years ago, through his studies of the decays of naturally occurring radioactive materials, Ernest Rutherford discovered that there are three main types of radioactive decay. He named them alpha, beta, and gamma decays after the first three letters of the Greek alphabet. Through subsequent experiments he discovered that alpha particles are the nuclei of ^4He atoms; beta particles are electrons, and gamma rays are quanta of electromagnetic radiation known as photons. In this chapter, the details of these three types of radioactive decay are explained and examples are provided of some of the uses and applications of radioactivity in society.

Chapter 6: *Fission I*, by Prof. Jennifer Klay, California Polytechnic State University San Luis Obispo

In the 1930s, Enrico Fermi, Lise Meitner, Otto Hahn, and Fritz Strassmann irradiated uranium with neutrons in hopes of producing new "transuranic" elements. Instead, they discovered the process of nuclear fission. Meitner and her nephew Otto Frisch explained the results of these experiments in terms of the process by which a heavy nucleus splits apart in to two or more fragments, releasing large amounts of energy and neutrons that can thus sustain a chain reaction. This chapter describes the history of these discoveries and the basics physics involved in the fission process.

Chapter 7: *Fission II*, by Prof. Andrew Stuchbery, Australian National University

After the discovery of the fission process, it did not take long for scientists and engineers to develop the first man-made sustained nuclear chain reaction in the so-called Chicago Pile 1. This led to the development of nuclear reactors as major sources of electrical power. In order to accomplish this, much had to be learned about neutron-induced fission cross sections, the energetics of fission, fission product properties, neutron interactions with materials, and conditions necessary to operate a nuclear chain reaction in a controlled and stable manner. Somewhat surprisingly, in the 1970s, it was discovered that approximately two billion years ago in what is now the nation of Gabon in Africa, conditions were such as to allow natural nuclear reactors to operate for lengthy periods of time in a self-regulating pulsed mode. The details of these topics are described in this chapter.

Chapter 8: *Manhattan Project*, by Prof. B. Cameron Reed, Alma College

During World War II, the United States undertook the development of fission-based nuclear weapons under what was called the *Manhattan Project*. Using fast neutron-induced fission cross sections that had only recently been measured, it was determined that weapons based on the fissions of ^{235}U and ^{239}Pu were both possible. Weapons of both types were produced and were dropped on the Japanese cities of Hiroshima and Nagasaki. This chapter describes the details of the *Manhattan Project* and of the competing German program.

Chapter 9: *Phenomenology of Neutron Interactions*, by Prof. Fred Wietfeldt, Tulane University

The neutron was discovered in 1932 by James Chadwick. Within a decade, Enrico Fermi and his colleagues demonstrated that a self-sustaining nuclear chain reaction could be produced via the neutron-induced fission of ^{235}U . Depending upon their energies, neutrons can interact with matter in a number of different ways. Knowledge of these interactions was key to the development of nuclear reactors, radiation safety, materials studies, and a variety of other applications. The basic principles of neutron interactions are described in this chapter.

Chapter 10: *Fissile and Fertile Fuels*, by Prof. Jennifer Shusterman, Hunter College

Neutron-induced fission is the process by which nuclear reactors produce energy. Materials that undergo fission after capturing a thermal neutron are called *fissile*. Examples of fissile isotopes include ^{233}U , ^{235}U , ^{239}Pu , and ^{241}Pu . *Fertile* materials are those that can be converted into fissile materials via neutron capture and beta decay. ^{232}Th and ^{238}U are examples of fertile materials. These isotopes are also referred to as fissionable since they can fission by high-energy neutrons. In this chapter, the chemical and nuclear properties of both fissile and fertile isotopes are described. The roles of each of these types of materials in the operations of nuclear reactors are also presented.

Chapter 11: *Fusion*, by Prof. Edward Morse, University of California at Berkeley

Fusion is the process by which two nuclei combine to produce one or more different nuclei. Due to the increase in nuclear binding energy per nucleon as one moves up in mass from hydrogen to iron, nuclear fusion reactions can produce enormous amounts of energy. The fusion of hydrogen into helium powers our Sun and most other stars. Subsequent fusion reactions produce all of the elements up to iron. Because of its potential as a commercial energy source, much theoretical and experimental effort has been devoted to developing a means to produce a controlled fusion reactor. The details of stellar fusion and of our attempts to develop large scale fusion facilities are discussed in this chapter.

Chapter 12: *Phenomenology of Gamma Ray and Charged Particles Interactions*, by Prof. Reina Maruyama, Yale University

An understanding of the ways in which gamma rays and charged particles interact with matter was required for the development of nuclear reactors, nuclear medicine, radiation safety, radiation detectors, and many other applications of nuclear science and engineering. Gamma rays interact with matter via three mechanisms: the photoelectric effect, Compton scattering, and pair production. Charged particles interact with matter primarily through collisions with atomic electrons producing ionization. The details of these processes are described in this chapter.

Chapter 13: *Radiation Sources*, by Prof. David Wehe, University of Michigan

Radiation sources come in many forms, from naturally occurring radioactive materials, to man-made sources, to accelerator-based sources. A large number of radioactive isotopes are used in applications ranging from nuclear medicine to oil-well logging. Similarly, accelerator-based sources of neutrons are utilized in materials studies and basic nuclear science. This chapter describes how and where many radioactive isotopes are produced and what they are used for.

Chapter 14: *Experimental Tools – Radiation Detectors*, by Prof. Ke Han, Shanghai Jiao Tong University

Our senses are not keen enough to register the interaction of a single neutron, proton, electron, or gamma ray. Thus, in order to study nuclear properties and to utilize ionizing radiation in applications such as nuclear reactor operations, radiation safety, nuclear medicine, and oil exploration, we rely on numerous types of radiation detectors. Some detectors measure the direct ionization produced by radiation; others measure the light produced when radiation interacts with certain materials; still others are sensitive to the heat produced by radiation interactions. In this chapter, the physics principles behind such detectors are described and examples are provided of a number of types of modern radiation detectors.

Chapter 15: *Experimental Tools- Accelerators*, by Prof. Alejandro Garcia, University of Washington

The range of the strong nuclear force is extremely short. Thus, in order for nuclear reactions to occur, the nuclei involved must essentially “touch.” To allow this to happen, one must overcome the Coulomb repulsion between nuclei. Today this is accomplished through the use of particle accelerators that can produce beams of any stable nuclear species (and a number of radioactive ones as well) at energies from electron-volts (eV's) up to trillions of eV's (TeV's). This chapter describes the physical principles underlying a variety of types of accelerators and provides examples of a number of currently operating facilities around the world.

Chapter 16: *Atomic and Hydrogen Bombs*, by Prof. Jim Napolitano, Temple University

The Manhattan Project resulted in the production of fission-based nuclear weapons commonly identified as *atomic bombs*. The fusion of light nuclei can produce more energy per unit mass than the fission of heavy nuclei. This idea is the basis for fusion-based weapons known as *hydrogen bombs* that can be much more powerful than fission weapons. In this chapter the basic physics as well as the unclassified details of how such weapons work is described.

The material contained in these chapters will provide the reader with a basic understanding of the sources of nuclear energy, radioactive decays, fission, and fusion. The experimental tools used to study and utilize nuclei are discussed. These chapters also describe how we have learned about the atomic nucleus and the ways in which it can be employed in the many applications described in later sections of this Encyclopedia.

What Is the Universe Made of?

From the Greek philosophers, the alchemists, to Mendeleev

The quest for understanding what the Universe is made of seems to be intrinsic to our species.

This curiosity, combined with the ability for organizing thoughts and discerning facts from fiction, has allowed humans to evolve from a hunter-gatherer society to its modern form, with all the associated advantages. Without understanding what things are made of, it is difficult to control them. So, it is not strange that one finds attempts to answer the question of the *composition of things* in the early history of human thought. Some of the Greek philosophers, including Aristotle, thought that all things on our planet were made of four elements: fire, water, air, and earth, adding quintessence for things in the heavens. However, this school thought of each of these as infinitely divisible. Leucippus, and his disciple, Democritus (c. 400 BCE), considered that indivisible units, *atomos*, were the basic components of all matter. However, without the rigor of modern experimental science, these ideas remained abstract for thousands of years. Interestingly, up to and during the middle ages, the alchemists were thought to have magical recipes that allowed *transmutation* of the more common elements into gold. This idea was also to remain dormant until the discoveries of the early 20th century.

Chemistry matured into a rigorous discipline through the renaissance. Toward the end of the 18th century, Lavoisier would give solid grounds to the atomic idea, identifying “simple substances” that could not be broken into parts by chemical reactions. In the 1800s, Dalton arrived at ways of determining the atomic weights of a couple dozen elements and an organizing chart in which they were classified by their atomic weight. It was Mendeleev, in 1869, who managed to organize 63 elements by increasing atomic weights and in columns, with similar chemical properties, showing periodicity. Mendeleev was able to predict elements that had not been discovered at the time or to correct the assigned atomic weight of some elements based on the periodic table. It is a wonderful example of how a correct organization can help discovery. Toward the end of the 19th century, J.J. Thomson would discover that the glow observed when high voltage was applied to metals under vacuum was caused by electrically-charged particles with a mass approximately 2000 times smaller than the mass of hydrogen. The electron would later become the principal character in explaining Mendeleev’s periodic table and remains considered an elementary particle to the present. J.J. Thomson conceived a *plum pudding model* for atoms, where electrons, with negative electric charge, would be confined by electric attraction to a positively charged substance that was thought to be uniformly distributed over the volume of the atom.

Rutherford and Chadwick, protons, neutrons, transmutations, basic nuclear properties, fission and fusion

In 1896, Becquerel discovered that salts of uranium emitted radiation that could be detected with photographic plates. Becquerel identified three types of radiation, now called alpha, beta, and gamma, according to the behavior of the radiation in magnetic fields. The alpha radiation was eventually identified as ions of helium, the beta radiation as electrons, and the gamma radiation as electromagnetic waves. In the early 1900s Rutherford and co-workers started studying the scattering of alpha particles from gold foils. With the plum pudding model for the gold atoms in his mind, Rutherford was amazed by the finding that alpha particles would backscatter: “It was almost as incredible as if you fired a 15-inch shell at a piece of tissue paper and it came back and hit you,” he later wrote. Rutherford realized that the positively charged part of atoms had to be made of a nucleus, of a size much smaller than the atom itself, but dominating its mass, and electrons orbiting around, determining the atomic size. More details are presented in (Krane, 2021). The chemical properties of the elements are mainly determined by the electrons. Rutherford also considered the nucleus as an agglomeration of protons and neutral particles of similar mass, explaining the existence of isotopes: elements with the same chemical properties but different masses. In 1933 Chadwick discovered the neutron, confirming these ideas. The neutron and proton have about the same mass and, apart from the electric charge, very similar properties within the nucleus. We refer to both neutrons and protons as *nucleons*.

Meanwhile, in 1905, considering how light is observed in different frames of reference, Einstein realized that matter and energy are connected by the now-famous formula: $E = mc^2$. This was essential in understanding subatomic phenomena.

Reflecting on the series of milestones summarized above, we can see that it is not just ideas on the constitution of things that are necessary to reach understanding: the edifice of concepts that are related to how things work is as essential, and sometimes indistinguishable, from the question on what things are made of.

Several puzzles came up as more knowledge was gained with respect to the constituents of atoms. An important one was that it was known from the study of electromagnetism that charged particles in orbits radiate energy. Thus, the model of atoms as electrons in orbits around a nucleus implied that they would lose energy by radiation, eventually collapsing into the nucleus. How could one then explain the stability of atoms? A few years before the discovery of the nucleus, Plank and Einstein had separately explained other observations by assuming that light is quantized into lumps, called photons. Each photon carries energy $E = h \nu$, with ν the frequency of the light, and h a constant, called Plank's constant. Bohr proposed a model in which the angular momentum of the electrons was restricted to having integer multiples of $\hbar = h/2\pi$ in orbits characterizing *quantum states*. Although Bohr's model did not explain why the angular momentum was *quantized* in this manner, it allowed explaining the stability of hydrogen, and matter in general. While excited states of atoms can decay by emission of photons, once the ground state is reached, there is no more radiation: the apparent contradiction with the expectation that particles in orbits radiate energy, was resolved by describing the electron by a *wave function* that determines a probability distribution. Rather than an orbit, we associate a static cloud to electrons in given quantum states. In the ground state there is not any real orbiting. The *electromagnetic interaction* induces transitions between excited states and lower-excitation states. In these *decays* the electrons switch from an initial to a final quantum state, each with a different associated cloud. Bohr's model also allowed to quantitatively explain the spectrum of light emitted by hydrogen (and other elements) when under electrical discharges. Sharp lines of well-defined frequency are predicted by the Bohr model, corresponding to electronic transitions between the allowed states, and they agreed well with observations at the time (Krane, 2021).

What ensued, the development of *quantum mechanics*, was to change our understanding of the behavior and constituents of nature at its most fundamental level. The hypotheses of the Bohr model were derived from a more general construct, developed among others, by Schrödinger and Heisenberg, that allowed understanding many other problems as well. The Coulomb potential from the nucleus generates a potential well and the equations of quantum mechanics show that there are *shells* with well-defined energies. Frequently, each shell can have a few quantum states, with different angular momenta. Remarkably, it was found that particles have an additional degree of freedom, called *spin*, which effectively works as an intrinsic amount of angular momentum, with a finite set of possible orientations. The electron, for example, is a spin- $\frac{1}{2}$ particle, and, in the absence of any orbital motion, will have two possible orientations, up and down, with angular momentum $\pm \hbar/2$ along a chosen axis. Another remarkable property, called the *Pauli exclusion principle*, is that particles with fractional spin (like the electron) cannot share quantum states. Thus, it is impossible to force two electrons with spin up to share all other quantum numbers. In the case of atoms, filled shells tend to be inert, yielding the noble elements. The alkali elements have a single electron in the last shell and tend to combine with elements that are missing one electron to fill a shell. Thus, the periodicity observed by Mendeleev and others is a result of the quantum behavior at atomic scales. More surprises came from quantum mechanics. Studying the union of relativity and quantum mechanics, Dirac showed the equations implied that for every existing particle there should exist a corresponding *anti-particle* with the same mass but opposite electric charge. The positron, the anti-particle of the electron was later found in experiments.

From the times of the discovery of the nucleus, about a century ago, our ideas of nuclear structure have evolved significantly. The nucleus has a size of a few *femtometers* (10^{-15} m), and, in agreement with what Rutherford thought, it is a factor of about 10^5 smaller than the atomic size. While the energies that bound electrons to atoms are on the order of a few *electron-volts* ($1 \text{ eV} = 1.6 \times 10^{-19}$ Joules), the corresponding quantity for nucleons is on the order of a few *Mega-eV* ($1 \text{ MeV} = 10^6 \text{ eV}$). The nucleus is held together by the nuclear force, much stronger than the electromagnetic force. This explains why the positively-charged protons do not fly away from the nucleus, yielding stable nuclei. The chart of nuclei, in Fig. 1, shows squares corresponding to nuclei, with the vertical axis as the number of protons, and the horizontal axis as the number of neutrons. Stable nuclei are shown in black.

Protons and neutrons in the nucleus satisfy the Pauli exclusion principle, just like electrons in the atom. Also, nuclei show excited quantum states, just like atoms show excited electronic states. Although, at first sight, one may imagine that the strong nuclear force, combined with the high density of nuclear matter, could lead to continual scattering and extremely short-lived states, it turns out that the scattering is blocked by the Pauli exclusion principle. The latter forbids scattering into occupied states, and the quantum states have long half-lives, exceeding, by orders of magnitude the time it takes for a nucleon to move through the nuclear volume. Although there is no external trapping potential (as in the atom, where the nucleus provides a Coulomb attraction) the nucleons can be considered as moving in an effective-potential well generated by the neighbors. For this reason, and accounting for the Pauli principle, light stable nuclei show an approximate neutron-to-proton ratio of 1:1, like ^{16}O with 8 protons and 8 neutrons. Fig. 2 shows a sketch of the nuclear potential with quantum states at different excitation energies. As the lower levels are filled, nucleons need to be placed into higher excitation energies, increasing the total energy. As a result, the most stable light-nuclei configurations correspond to nuclei with equal number of protons and neutrons. For the heavier nuclei, the electrostatic repulsion becomes more important, which explains why heavier stable nuclei tend to have a higher fraction of neutrons than light stable nuclei. The nucleus ^{208}Pb , for example, has 82 protons and 126 neutrons. This trend can be noticed following the stable nuclei (black squares) in Fig. 1 as a slope of approximately 1 at the light-nuclei side of the chart, and a smaller slope as nuclei get heavier.

Free neutrons turn out to be unstable, converting into a proton, an electron, and an anti-neutrino, a particle about which we will say more below. What is the origin of this lack of stability? We have discussed how the electromagnetic interaction mediates decays from excited states of atoms toward lower-energy states. In a similar way the weak interaction mediates radioactive decays. These

Fig. 1 Chart of nuclei and stellar processes that produce them. The vertical axis is the number of protons, Z , while the horizontal axis is the number of neutrons, N . Each square corresponds to a given nucleus. The chart starts at the bottom left with hydrogen. Stable nuclei are shown in black. Green is used for nuclei for which something has been measured. In yellow are shown nuclei for which we only have calculations, but no measurements. The uncolored nuclei, located beyond the *drip lines*, are not held together by the strong force. The labels indicate stellar processes that involve the nuclei in the different regions. Courtesy: Hendrik Schatz.

Fig. 2 Sketches of the effect of the Pauli exclusion principle in light nuclei. Red (green) indicates filled (empty) quantum states. The difference between the proton and neutron potentials is due to the electrostatic repulsion. Left: for a given total number of nucleons, identical number of protons and neutrons minimizes the total energy. Middle: a proton-rich nucleus can be unstable and decay by β^+ emission ($p \rightarrow n + e^+ + \nu$). Right: a neutron-rich nucleus can be unstable and decay by β^- emission ($n \rightarrow p + e^- + \bar{\nu}$).

radioactive decays are responsible for the beta radiation observed in the early days. Before the discovery of the neutron, some thought that electrons composing the beta radiation existed in the nucleus before ejection, and that the emission resembled that of alpha-particle emission. In this scenario for radioactive decays, an atom of ^{14}N , for example, would be composed of 14 protons and 7 electrons in the nucleus, and an additional 7 electrons in atomic orbits. This idea was eventually rejected: one consequence of quantum mechanics is that there is a relation between the momentum of particles and their spatial localization, known as the uncertainty principle. For the example at hand, given the small size of the nucleus, it would imply that beta-decay electrons should have much higher energies than were observed. The necessary conclusion was that the beta particles were produced at the time of decays. With the discovery of the neutron, it became clear that ^{14}N , in our example, is composed of 7 protons and 7 neutrons in the nucleus and 7 atomic electrons. While free neutrons decay, they are forbidden to do so by energy conservation in the case of ^{14}N , which is a stable nucleus. The transformation within the nucleus would require placing a proton in a quantum state that is already occupied by other protons, violating the Pauli principle, as shown in Fig. 2. Thus, stable nuclei work as neutron storage places, where neutrons can remain indefinitely, protected from decay. Free protons, on the other hand, are stable. The mass of the neutron is higher than the mass of the proton, so, protons are protected from decaying into a neutron, a positron, and a neutrino, by energy conservation. On the other hand, in proton-rich nuclei, the Pauli exclusion principle implies that protons can get transformed into neutrons without violating energy conservation. In this case the weak interaction mediates the transformation of a proton into a neutron, a positron (the anti-particle of the electron), and a neutrino. This is called β^+ decay, while the decay of the neutron is called β^- decay. Thus, proton-rich nuclei (above the line of stability) decay by β^+ emission and/or electron capture, while neutron-rich nuclei (below the line of stability), decay by β^- emission. (See Fig. 2.) More details on radioactive decays are given in (Previtali, 2021).

The nucleus is a *saturated medium*, very hard to compress, like a liquid. In fact, an early successful model described the nucleus as a liquid drop. The masses of nuclei are significantly affected by the interactions between the nucleons. The difference between the sum of the masses of the constituent protons and neutrons and the mass of the nucleus is called the *binding energy*:

$$\text{B.E.} = Z m_p c^2 + N m_n c^2 - m(Z, N) c^2$$

where m_p , m_n , $m(Z, N)$ are the masses of, respectively, a free proton, a free neutron, and a given nucleus with Z protons and N neutrons. The binding energy is described in more detail in Klay (2021). Here, it will suffice to indicate that the *binding energy per nucleon* is approximately constant at about 8 MeV/nucleon for a large range of nuclei. However, very light nuclei and very heavy nuclei have smaller binding energies than the average. Thus, nuclei can undergo fission or fusion, gain average binding energy, and liberate energy. This is the reason why fission can be used for nuclear reactors and weapons, as described in more detail in Klay (2021) and Wark (2021). Alternatively, the large increase of the binding energy per nucleon between hydrogen and helium can be used to liberate energy via fusion of light elements, as addressed in Morse (2021). The Sun shines from fusion reactions and it is hoped that in a not-too-distant future artificial fusion reactors will exploit this phenomenon in a controlled way.

Nuclear science became more sophisticated and accurate at describing phenomena through the 20th century. However, the problem of calculating nuclear structure is of phenomenal complexity. Nuclear science shares with atomic and solid-state physics the difficulties imposed by the *many-body problem*, but, in addition, the interaction between the nucleons is not given by a simple formula, like the Coulomb potential, for the atomic case. Many ingenious ideas have been used to overcome these difficulties, leading to *phenomenological* approximations that were tuned to reproduce data around a particular set of phenomena and section of the nuclear chart. Up until recently, *ab initio calculations*, that start from the very basic interactions and can explain all phenomena within the same framework, have not been possible. These calculations are now possible for light nuclei, and there are new ideas to extend this revolution in understanding for heavier nuclei. Accelerator facilities for exploring nuclei far from stability are being built to carry out experiments that will eventually allow doubling the number of nuclei accessible for experimentation.

Quarks and other elementary particles

The tale we have told so far seems to indicate that the answer to the question of what the Universe is made of is “protons, neutrons, and electrons.” With the advent of accelerators of higher energies, during the second half of the 20th century, subatomic physicists discovered a myriad of new particles and phenomena. Today we understand that all these particles are made only of the elementary components shown in Fig. 3. These are the modern equivalent of the four elements of Aristotelian days, but are also indivisible, as Democritus wanted, as far as we know. The six quarks and their anti-quarks get combined to make *baryons* with three quarks, qqq , and *mesons* with a quark and an anti-quark, $q\bar{q}$. The proton and neutron turned out to be baryons, composed of two up and one down quark for the proton, and one up and two down quarks for the neutron. There are many other baryons and mesons, but none of them are stable. The leptons, an example of which is the electron, are lighter (within each column) and insensitive to the strong force. A set of the leptons called neutrinos that were mentioned above in the context of beta decay, are electrically neutral and only sensitive to the weak interaction. Either a neutrino or an anti-neutrino is always emitted in nuclear beta decay.

All quarks and leptons are spin- $\frac{1}{2}$ particles. In addition, the *gauge bosons*, are responsible for the interactions. Their spin is an integer number and they are not affected by the Pauli exclusion principle. Finally, there is the Higgs boson, responsible for the masses of the other particles. It had been thought of in the 1960s, when it was predicted by a theory that seemed abstract at the time. The Higgs boson was discovered experimentally in 2012. This finding represented the culmination of many experiments that have confirmed the workings of the theory, which has now become the standard lore and is called the *Standard Model*.

← spin-1/2 particles →				← bosons →		
Quarks	mass charge spin					
	2.4 MeV/c ² +2/3 1/2 up	1.3 GeV/c ² +2/3 1/2 charm	173 GeV/c ² +2/3 1/2 top	0 0 1 gluon	125 GeV/c ² 0 0 Higgs

Fig. 3 The elementary particles. Under each square, the top left has a list of the mass, charge, and spin of each particle. The three left-most columns are the elementary fermions, all spin-1/2 particles. Protons and neutrons are made of up and down quarks: $p \equiv uud$, $n \equiv ddu$. The fourth column lists the gauge bosons, responsible for the interactions. The last column contains only the Higgs particle, responsible for the masses of all the other particles.

Where were the elements produced?

We live in an expanding Universe. First evidence for this came in the late 1920s when Hubble noticed that all stars were moving away from us at a speed proportional to their distance from the Solar system. The rate of expansion can be calculated from the proportionality. It then followed that, at an earlier epoch, the Universe must have been smaller, denser, and hotter. The primordial explosion is called the Big Bang. We now believe that it occurred approximately 13.7 billion years ago. For reference, the oldest rocks on Earth are about 4 billion years old. Initially the Universe resembled a hot soup, with all elementary particles in equilibrium at very high temperatures. As the Universe expanded and cooled down, quarks coalesced into protons and neutrons. As soon as formed, neutrons started decaying, but, before they all decayed, some combined with protons to form ${}^4\text{He}$. The primordial abundance of ${}^4\text{He}$ was about 25% (by mass) and the rest was mostly hydrogen, with traces (less than 0.1%) of deuterium (${}^2\text{H}$), ${}^3\text{He}$ and ${}^7\text{Li}$. At this point electrons were moving too fast to get trapped into atoms, so the Universe still consisted of a plasma. Photons could not move freely through this plasma. For reference, photons take about 10,000 years to get from the center of the Sun to its surface. When the Universe was about 380,000 years old, we believe its temperature was approximately 3000 K, which was cold enough for atoms to form, allowing photons to decouple from the plasma. These photons permeate the whole Universe and can still be seen today as the *cosmic microwave background* (CMB) radiation. Due to the expansion of the Universe, the characteristic temperature of the CMB is now approximately 2.7 K, a factor of approximately 1000 colder than when emitted.

If the primordial elements were mainly hydrogen and helium, where were the rest of the elements made? Many elements are produced by the nuclear reactions that power stars. Typically, the initial gas that makes the star will heat up as it gets denser under gravity. Once the temperature is such that the kinetic energy of the particles allows for nuclear reactions, hydrogen gets transformed into helium via processes that involve several steps. An example of the latter is the, so-called, pp-chain, shown in Fig. 4, which fuels the Sun. Once the hydrogen fuel is consumed to a point that allows for the star to compress further under gravity, helium can be burned, and heavier elements produced. The fate of a star depends on its mass. For the Sun, the helium burning will end with an expansion that will make it puff into a *Red Giant*, extending out to engulfing the orbits of the closer planets. Eventually, some of the mass will collapse again under gravity, leaving behind a *White Dwarf*, with a radius similar to the Earth's radius. Heavier stars continue beyond the helium burning, developing a layered structure, as shown in Fig. 4. Many elements are made in explosive scenarios, like the collapse of an old star under gravity. Fig. 1 indicates sections of the chart of nuclides that are produced in different scenarios. The p-process is the slow capture of protons (extending near stability) and the rp-process, is the *rapid* proton capture, occurring when capture reaction rates are faster than the times for the radioactive decays of the isotopes produced in single-proton captures on stable isotopes. The p-process occurs most likely in core collapse or type Ia supernovae as a photodisintegration process, while the rp process is thought to take place in X-Ray Bursts (XRBs), X-ray pulsars and novae. The s-process is the slow capture of neutrons (like the p-process, near stability, but to the neutron-rich side.) It occurs mainly late in the life of stars after they go through the Red Giant phase. The r-process is the rapid capture of neutrons: this process occurs in sites with very large densities of neutrons, and these nuclei are much further into the neutron-rich area of the chart. While calculations indicated that the collapse of stars producing supernovae were good candidates for the r-process, they seemed to indicate that the neutron densities were not high enough. In 2017, the LIGO collaboration, set up to detect gravitational waves that come from the cosmos, identified the collapse of two neutron stars. LIGO alerted other observatories to orient their instruments in the direction of origin of the gravity wave, and soon images on the different parts of the electromagnetic spectrum (x-rays, infrared, UV, etc.) were recorded by approximately 70 instruments. The results identified the possible production of many r-process nuclei in the collapse of a binary system of two neutron stars. It was a spectacular event! This type of collaborative effort is now called *multi-messenger astronomy* and has become a very fertile field of research.

The pp-chain, mentioned above, is particularly important for us because it fuels the Sun via the conversion of four protons into ${}^4\text{He}$. In this process two of the protons are converted to neutrons. As we indicated above, this does not happen for free protons, but

Fig. 4 Left: the pp-chain that dominates the energy generation in the Sun. Right: the layered structure developed by aging massive stars.

can happen through intermediary nuclear reactions in the Sun and other stars. The reactions involve the weak interaction, which makes the process slow and allows the Sun to yield energy at a rate slow enough to last for several billion years.

More knowledge, more questions: Dark matter and dark energy

Most of the mass in our planetary system is in the Sun, so it was expected that stars would account for most of the mass of the Universe. When measurements of the rotational velocities of stars through the Andromeda galaxy were compared to expectations, assuming the approximately known masses of the stars, it was discovered that there is, in addition to the stars, a much larger source of gravity, approximately equivalent to six times the mass of the stars. This is called *Dark Matter*. Using our understanding of primordial nucleosynthesis, we have concluded that it *cannot be baryonic* matter, like protons and neutrons, or electrons. The name thus reflects our lack of understanding of what the substance really is. It has been considered that this could be an artifact due, perhaps, to inaccuracies in our understanding of gravity itself. However, so far, the proposed models for modified gravity have been rejected by experiments. There are many on-going searches to try to identify the nature of Dark Matter.

We mentioned above that in the late 1920s, the Universe was found to be expanding. A projectile that is given an initial kinetic energy in the gravitational field of the Earth will lose kinetic energy as it moves out. Thus, it was expected that we would eventually find out that the Universe's expansion was slowing down. However, in the 1990s it was found that the expansion is actually accelerating. It is thought that this is due to a substance called *Dark Energy*. In terms of the Einstein energy-mass relation, the implication is that approximately 68% of the mass-energy of the Universe is in the form of Dark Energy.

Both Dark Matter and Dark Energy are considered at the top of the list of important unresolved problems in fundamental physics. As we can see, over the years, as we have improved our understanding of what the Universe is made of, we have also gotten to realize that 68% is Dark Energy, 27% is Dark Matter, and the stuff we know rather well, protons, neutrons, and electrons, makes only approximately 5% of the mass-energy balance of the Universe.

This section was supposed to describe what the Universe is made of. We know quite well what the Universe around us is made of: ultimately the particles of Fig. 3, in different combinations. We also know a fair amount about the forces between these particles and how they combine to yield the diversity of nuclei and elements we find around us. However, the adventure toward fully understanding the answer to the title of this section continues and promises more surprises as we unravel these mysteries.

Glossary

Absorber Any material that stops or diminishes the intensity of the ionizing radiation. A thin sheet of paper or metal will stop or attenuate alpha particles and all except the most energetic beta particles. Lead, steel, copper, aluminum, and concrete attenuate gamma-rays.

Cathode rays A stream of electrons emitted by the cathode, or negative electrode, of a gas-discharge tube or by a hot filament in a vacuum tube, such as an old television tube.

Fluorescence Emission of light by a substance that has absorbed light or other electromagnetic radiation (X-rays, ultraviolet light). Fluorescent substances cease to glow nearly immediately when the incident radiation source stops.

Half-life The time it takes for a quantity of the atoms of a radioactive isotope to be reduced by half. Also called semi-disintegration period.

Ionization Removal of one or more electrons from an atom, leaving it positively charged.

Ionizing radiation Any radiation that is capable of producing ions either directly or indirectly. X-rays, neutrons, alpha, beta, and gamma radiation produce ionization.

Phosphorescence Ability of some materials to absorb light and re-emit light sometime after the exciting light source has been removed. Phosphorescent materials continue to emit light for a noticeable time after the incident radiation ceases.

Transmutation Transformation of one element into a different element by an induced nuclear reaction or a spontaneous nuclear decay.

Introduction

Radioactivity is a phenomenon produced in certain unstable atoms in which nuclei transform by emitting particles and/or electromagnetic radiation. Most of the atomic nuclei found in Nature are stable. However, some nuclei are unstable, turning into another kind while emitting radiation spontaneously; these radioactive nuclei decay over time. Their emission occurs at very variable times, from a fraction of a second up to billions of years. A radioactive atom has exactly the same physical, chemical or biological properties than an ordinary atom, except at the time it decays.

The energetic radiation emitted has been classified using the first three letters of the Greek alphabet: alpha (α), beta (β) and gamma (γ). Alpha radiation is composed of helium nuclei, beta radiation of positively- or negatively charged electrons and gamma radiation of high-energy photons.

Natural radioactivity was discovered at the end of the 19th century, however, since its formation approximately 4600 million years ago, the Earth has been radioactive. Consequently, from its origins, life on our planet was always exposed to a certain level of natural radiation, coming from the decay of radioactive nuclei or produced by cosmic rays.

Natural radioactive isotopes are found in air, water and soil in the environment, including in our bodies and in food. They can be classified as: (i) “*primordial*” radioisotopes, released in the birth and death of stars and created before the formation of the Earth, or (ii) “*cosmogenic*” radioisotopes, produced as the result of reactions between the nuclei of the gases that constitute the atmosphere and the galactic and solar cosmic rays that fall on Earth.

Uranium 238, uranium 235, thorium 232 and potassium 40 are primordial radioisotopes and can still be found in our planet because their half-lives are measured in billions of years. The rest of short half-lives radioactive isotopes produced at the time of the creation of the Universe have gradually disappeared.

Uranium and thorium are the heaviest elements that exist naturally in the Earth crust. The three radioisotopes (238U, 235U, 232Th) disintegrate spontaneously by means of different radioactive processes giving origin to other descendent radioisotopes. All of them, including radon, which is an inert gas, are the main sources of natural radioactivity. They generate what is called telluric radiation: gamma radiation emitted by these radioisotopes found in rocks and in the building materials. Potassium 40 (40K) forms part of all human bodies and it is present in food: milk, cheese, dairy products, vegetables and fruits.

Carbon 14 (14C) and tritium (3H), an isotope of hydrogen, Beryllium 7 (7Be), Beryllium 10 (10Be), are examples of radioisotopes of cosmogenic origin. The existence of these nuclei is permanent on Earth since they are constantly regenerated due to the bombardment of cosmic rays. The half-life of 14C is 5730 years. Plants absorb atoms of 14C along with ordinary carbon meaning that all living matter contains traces of this radioisotope. Due to these properties, Carbon-14 dating is a method that allows to precisely estimate the age of certain archeological objects of a biological origin up to about 50,000 years old.

Natural radioactivity, either from primordial or cosmogenic origins, is present in our everyday lives; it is an integral part of our environment. The air we breathe, the food we eat and our bodies contain radioactive isotopes.

Since the discovery of artificial radioactivity in 1934, new sources of radioactivity have been added to the list of natural sources.

The advent of the nuclear age, in the middle of the 20th century, brought about the production of new radioisotopes, now created by man, among others: cesium 137 (137Cs), strontium 90 (90Sr) and iodine 131 (131I), which are incidental waste products of the military and industrial nuclear development. These radioisotopes, called anthropogenic by their origin, globally added small quantities to the inventory of natural radioactivity present in the environment today.

The anthropological releases of radioactive materials to the air that occurred in the past, were of two kinds: (i) deliberate, due to the many atmospheric nuclear-weapon tests which began in 1950 and reached their peak in 1962, and (ii) involuntary, mainly as the result of the nuclear plant accidents in Chernobyl (1986) and in Fukushima (2011).

Fortunately, on the other hand, the use of artificially-created radioisotopes have allowed important advances in different fields. The most significant results are in medicine, where radioisotopes like: iodine 131 (131I), molybdenum/technetium 99 (99Mo-Tc), cobalt 60 (60Co), fluorine 18 (18F), are used in a variety of beneficial applications of radiation for health diagnoses and therapies.

It is important to emphasize that the exposure to radiation in medical applications, for example, in X-ray radiographs, exceeds the exposure caused by natural radioactivity sources. The effects of all these radiations can be harmful to living cells but, when used in the right way, they have a wide range of beneficial applications.

In this article, we will explore the relevant historical facts from 1895 until the 1930s: hypotheses, experimental researches, questions, discussions and controversies that led the discovery of natural and artificial radioactivity.

Natural radioactivity

Roentgen—December 28, 1895

X-rays were discovered in 1895 by Wilhelm Roentgen when he was working with electrical current flow in a cathode-ray tube. During one of his experiments, he covered the tube with a black paper. The experimental room was completely dark. However, he observed that a screen painted with fluorescent salt, which was on a near table for an independent experiment, gave off light every time an electrical discharge occurred. This phenomenon happened in spite of the fact that neither visible light nor cathode rays could directly reach the screen.

The “unknown radiation” originated from the location where the cathode rays (electrons) hit the glass tube or the anode plate inside the tube. It could pass through materials opaque to light, travel across the room, and activate a fluorescent screen. Roentgen was surprised about his finding which happened just by chance. In view of its uncertain nature, he thus gave the rays somewhat mysterious name of “*X-rays*,” though it also became known as Roentgen rays. Now, we know that X-rays are emitted when electrons lose their velocity due to its interactions with matter (Bremsstrahlung).

Roentgen began to study extensively the new discovered rays in order to determine some of its important properties. His experiments revealed that many materials, were transparent to the X-rays to some degree. This transparency decreased with increasing density of the material. Roentgen was unable to detect appreciable reflection or refraction of the rays, nor was he able to deflect them with a magnetic field. He found that X-rays made photographic plates black.

Roentgen recorded his first observation on November 8, 1895, and he announced the discovery of X-rays on December 28, 1895 in a preliminary paper sent to the secretary of the Physical-Medical Society of Würzburg (Roentgen, 1895). Then, he wrote only two more papers on X-rays (Roentgen, 1896, 1897). The scan of his wife’s hand was published in newspapers all around the world and caused quite a commotion. As of mid-January 1896, doctors and physicist in all Western countries were using the X-ray apparatus described by Roentgen to perform scans of their own and, at the end of December 1896, the bones of a broken arm were joined using X-rays. He was awarded the first Nobel Prize in Physics in 1901, for the discovery of X-rays.

Antoine Henri Becquerel—end of February–March 1, 1896

The discovery of X-rays by Roentgen was a matter of chance. The observation of radioactivity, however, was definitely the consequence of a mistake and a following accidental event.

Henri Becquerel decided to study the existence of a possible relation between X-rays and the phosphorescence phenomena in uranium salts. In those days, he thought, mistakenly, that minerals made phosphorescent by visible light, might emit X-rays. Becquerel had a wide collection of minerals, many of which showed phosphorescence. In order to test his hypotheses, he placed a phosphorescent uranium salt on top a photographic plate wrapped in black paper (to protect it from direct light) and exposed the whole set-up to strong sunshine for several hours. When he developed the plate, it showed the expected blackening with the image of the uranium salt. Initially, [Becquerel \(1896a\)](#) concluded that this result confirmed his hypotheses and published his results.

He wanted to continue the experiments but the sun did not shine in Paris for a few days at the end of February 1896. Since he was unable to expose another uranium salt to the sun, he put away the mineral placed on top of a fresh sheet of photographic plate together in a dark drawer of a cabinet. A few days later, he developed the photographic plate expecting a weak image and he was surprised to find out that it was totally black as intense as in the original sunlight experiment ([Becquerel, 1896b](#)). He discovered that penetrative rays emitted by the salt left an impression on the plate. With this new evidence, he had to change his previous conclusions: the exposure from the uranium salt came even in the dark and it was not related to sunlight ([Becquerel, 1896c](#)).

Becquerel systematically performed further experiments by using a variety of uranium minerals. He determined that several uranium salts, whether phosphorescent or not, as well as metallic uranium had the same property ([Becquerel, 1896c,d](#)). Therefore, he established that the radiation was an intrinsic characteristic of the uranium and it ionized air, as well as X-rays do. [Becquerel \(1896e\)](#) referred to the discovered penetrative rays as “uranic rays.”

Marie Skłodowska Curie and Pierre Curie—1897

Marie Skłodowska was born in Warsaw and she came to graduate school in Paris, because women in her country were not admitted to the University. She had married Pierre Curie in 1895, who had a well-known reputation working on piezoelectricity and magnetism. In November 1897, Marie Curie wanted to make her doctoral thesis in physics. Henri Becquerel recommended her to continue with his research on uranium minerals as the subject for her doctoral thesis.

She decided to conduct a systematic research on the “uranic rays” found in a number of elements, compounds and minerals. She measured quantitatively the ionization in the air created by the radiation of the uranium samples. The experimental setup consisted in an electrometer with a piezoelectric quartz developed by Pierre and his brother Jacques Curie, capable of measuring very low values of electrical current.

The experiments confirmed that the intensity of the radiation emitted by the uranium minerals was proportional to the amount of uranium present in it. In her systematic measurements, she also found that thorium minerals also behaved similar to uranium minerals ([Curie, 1898](#)). The emission of the “uranic rays” was a more general property of matter. Marie Curie proposed the name “radioactivity” to describe this phenomenon. She also noted that radioactivity appeared to be an atomic property.

Pierre Curie understood the importance of the results of these experiments, so he left his research on crystals and decided to join his wife in the search for the unknown radioactive element.

After examining several uranium minerals, such as pitchblende (uranium oxide) and chalcocite (copper and uranium phosphate), Marie Curie and her husband found that these minerals were much more radioactive than one would expected from the uranium content. The conclusion was that it contained other unknown radioactive components.

Starting from several tons of uranium mineral pitchblende, Marie and Pierre Curie succeeded in isolating, and thus discovered, two previously unknown radioactive elements, present in trace amounts in pitchblende. They announced the existence of a new element, named “polonium” (Po) in honor of Marie’s native country Poland, in a paper published on July 1898 ([Curie and Curie, 1898](#)). In this publication, the Curies used for the first time the word “radioactivity” even though H. Becquerel discovered it.

Later in the same year, the Curies, with the help of G. Bemont, announced the existence of a second new element, which they called “radium” (Ra) for its high intense radioactivity ([Curie et al., 1898](#)). Polonium was 60 times more radioactive than uranium and radium was 400 times more. Radium half-life is 1600 years very much shorter than 4.5×10^9 years of the uranium (^{238}U) half-life, therefore, for a same weight, its radiation is much more intense. There is one gram of radium in about three tons of natural uranium.

Pierre and Marie Curie continued their investigations trying to find new radioactive elements in pitchblende together with members of their research group. André Debierne announced the discovery a new radioactive element in a publication ([Debierne, 1899](#)). Later, this element became known as actinium.

Henri Becquerel, Marie and Pierre Curie won the 1903 Nobel Prize in Physics. Becquerel was awarded this prize for the discovery of spontaneous radioactivity and the Curies for their joint researches on these radiation phenomena. In 1911, Marie Curie won a second Nobel Prize, this time in Chemistry, for the discovery of the elements radium and polonium.

Types and properties of nuclear radiation

Ernest Rutherford— α , β , γ rays—1899

After the discovery of radioactivity, many physicists all over the world devoted their lives to study and to understand the properties of the different types of radiation emitted by radioactive nuclei.

In October 1895, Ernest Rutherford, a 24 year-old young New Zealander, arrived in England to work at the Cavendish Laboratory in Cambridge. A month after his arrival, the announcement of the discovery of X-rays by Roentgen shook the scientific world and public opinion. In 1897, J.J. Thomson guided his young assistant on the Becquerel rays that had just startled the scientific world.

Rutherford began his studies on the radiation emitted by uranium in 1898. His experiments consisted of studying the ionization of gases produced by this radiation. In 1899, the results led him to conclude that radioactivity is not homogeneous and must have at least two components: (a) a component which ionizes very heavily, but it is absorbed in a single sheet of paper, and (b) a component capable of penetrating several mm of Cu, Al, etc., which causes much less ionization. In summary, depending on their ability to penetrate matter and ionize air, Rutherford (1899) called them: alpha-radiation and beta-radiation, respectively.

At the end of 1899, several experiments performed in Germany (Giesel, 1899), Austria (Meyer and Schweidler, 1899a,b) and France (Becquerel 1899), demonstrated that a part of the rays emitted by radium were easily deflected in the presence of a magnetic field. From the direction of deflection, it was concluded that the “deviating” rays, named β -radiation by Rutherford, behaved like negatively charged particles. Curie and Curie (1900) demonstrated directly that the β -rays from radium had a negative charge. Becquerel (1900a), in an independent experiment, showed that the same rays were deflected in an electric field in the same direction as cathode rays.

Knowing that beta-rays were deflected by both magnetic and electric fields, Becquerel proved that they were electrons. He measured the charge-mass ratio (e/m) for these rays by the method that J.J. Thomson had used to study cathode rays and identify the electron. He found that the ratio was the same as Thomson’s electrons; therefore, Becquerel (1900b,c) suggested that the beta-radiation was, in fact, made out of electrons.

In 1900, Villard found that radium salts emitted an extremely penetrating radiation capable of being detected through a thin layer of lead or about 20 cm of iron (Villard, 1900). In 1903, Rutherford proposed to call gamma-radiation to Villard’s discovery because it was much more penetrating than alpha-radiation and beta-radiation that he had already distinguished and named in 1899. Shortly the gamma-radiation was proven to be electromagnetic radiation just as light, but with much shorter wavelengths and higher energies.

Fig. 1 displays a sketch similar to the one presented by Marie Curie in her Ph.-D thesis published in June 1903. The three kinds of rays (α , β and γ) emitted by a radium source, have different trajectories in the presence of a magnetic field. Alpha-rays are helium nuclei positively charged, thus they deflect to the left; beta-rays are electrons much lighter and negatively charged, thus they deflect

Fig. 1 A scheme similar to that presented by Marie Skłodowska-Curie in her Ph.D. thesis to describe some properties of the three kinds of radiation (α , β and γ) emitted by a radioactive source. They have different trajectories in a magnetic field. Alpha-rays, which are helium nuclei positively charged, deflect to left; beta-rays are electrons much lighter and negatively charged, deflect to right, and gamma-rays, which are very high-energy electromagnetic waves, do not deflect in the magnetic field since they are neutral.

to the right; and gamma-rays, which are very high-energy electromagnetic waves do not deflect in the magnetic field since they are neutral.

The definitive identification of alpha-radiation took a much longer time. Ramsay and Soddy (1903a,b) performed experiments in London and showed that helium is produced from radium emission. It was in 1909 when Rutherford and Royds (1909) performed an experiment to demonstrate that alpha particles were identical to double ionized helium. They put a large quantity of purified radon gas, an alpha-emitter, enclosed in a glass tube with very thin walls (0.01 mm thick) enough to allow the alpha particles go through to another evacuated tube surrounded the thin-walled tube containing radon. After a week, the whole spectrum of helium was visible. The alpha particles emitted by the radon gas gave rise to the characteristic helium spectrum.

Ernest Rutherford and Frederick Soddy—uranium decay series—1902

In the autumn of 1898, Ernest Rutherford was appointed professor of physics at McGill University in Montreal despite being only 27 years old. A few years later in 1901, Frederick Soddy, a young talented English chemist, joined Rutherford to work on radioactivity.

In 1902, while doing experiments on thorium compounds, Rutherford and Soddy discovered that radioactivity was associated with changes inside the atom that transformed thorium into a different element. They found that thorium continually generated a chemically different substance that was intensely radioactive. The radioactivity eventually made the new element disappear. They identified the radioactive emanation of radium as radon and demonstrated experimentally that radioactivity is the spontaneous transformation of one element into another through the emission of radiation (Rutherford and Soddy, 1902a,b, 1903).

The polonium and radium extracted from pitchblende and discovered by Pierre and Marie Curie were also direct descendants of the uranium it contained. When uranium and thorium emitted alpha and beta particles, they decayed into different elements. This sequence of transformations later was called the “*natural decay series*.” By studying the chemistry of the natural decay series of uranium (U) and thorium (Th), 30 new radioactive isotopes were discovered, of which radium (Ra) was the best known. During these times, 1903, the existence of a nucleus inside the atom was unknown. This was proposed by Rutherford in 1911 to explain the results of the series of experiments performed together with H. Geiger and E. Marsden.

The existence of isotopes was proposed by Soddy in 1913. He discovered that all radioactive preparations were not unique elements, but rather that some of them were variants of known elements. In other words, certain atoms could have the same chemical properties, but have different properties when it came to radioactivity.

Soddy (1913) coined the term “*isotopes*” in a letter to the editor published that year. Isotopes were atoms of certain elements that might exist in forms that differed on atomic weight while being indistinguishable and inseparable chemically, and therefore, they should occupy the same position in the Periodic Table.

We must remember that neutrons were not discovered until 1930. Nowadays, isotopes are atoms of the same nuclear charge but different mass; namely, they contain the same number of protons (are the same element) but different numbers of neutrons. From the detailed chemistry of the decay series Soddy, and others, noticed that the chemistry of the daughter element was connected with the emitted radiation.

Therefore, the researchers noticed that alpha particle emission moved the element two places down the Periodic Table, while beta emission moved the corresponding element one place up the Table.

Rutherford and Soddy obtained Nobel prizes in Chemistry. Ernest Rutherford won the Nobel Prize in 1908, thanks to these discoveries in the area of the disintegration of the elements and in the chemistry of the radioactive elements. Frederick Soddy won the Nobel Prize in Chemistry in 1921 for his investigations in the chemistry of radioactive substances and the origin and nature of isotopes.

The natural decay series provided valuable evidence for the idea that radioactivity accompanies atomic transmutation, one of the fundamental principles of subatomic physics. The disintegration of atoms of radioactive elements was a key discovery at that time, as atoms were believed to be a class of indestructible matter.

Exponential decay law—1903

The discovery of natural radioactivity by Becquerel in 1896 marked the beginning of the study of the atomic nucleus. Becquerel's observations of radioactivity were only qualitative. Pierre and Marie Curie (1902) mistakenly believed that each atom of radioactive material worked as a constant energy source, drawing it from the environment. They claimed that the radioactivity of uranium, thorium and radium did not change in time based on experiments for several years. It is known now that the half-lives of uranium and thorium are of the order of billions of years, and it is 1600 years for radium. Therefore, these half-lives are too long to obtain a measurable variation of their radioactivity even in months or years.

On the contrary, between 1901 and 1903, Rutherford and Soddy (1902a,b, 1903) derived a quantitative law from their experiments performed on thorium. Watching the process, they discovered that the decay of a radioactive element was not constant but decreased exponentially with time following the law $N(t) = N_0 e^{-\lambda t}$, where $N(t)$ is the number of radioactive nuclei at time t , N_0 is the number at $t = 0$ and λ is the probability for any particular nucleus to decay per unit time. The period or “half-life” for a specific radioactive nucleus is defined as $T = \ln 2 / \lambda = 0.693 / \lambda$, and represents the period of time in which half of the nuclei of a particular radioactive element disintegrate.

Fig. 2 shows a plot of the radioactive exponential decay law. It can be observed that the number of nuclei in a radioactive sample at a given time t , $N(t)$, reduces to one-half of the initial value N_0 after a time T (half-life). After two half-lives $2T$, N_0 reduces to one-fourth; after three half-lives $3T$, it reduces to one-eighth, and so on.

Rutherford and Soddy proved that the half-life was a characteristic property of each radioactive element having its own intrinsic half-life. If the radioactive atoms resulting from such a decay are also radioactive, they will in turn decay with their own “half-life.” This is the case for the disintegration of uranium and the thorium nuclei where we have a whole series of successive decays.

Half-lives can range from a fraction of a second to billions of years. The exponential time dependence is a characteristic of all radioactivity and indicates that it is a statistical random phenomenon. The exponential behavior observed by Rutherford and Soddy demonstrated that radioactivity is an irreversible transmutation process of matter.

Development of artificial radioactivity

James Chadwick—the neutron—February 1932

Prior to the discovery of the neutron, it was thought that atomic nuclei were made of protons, α particles and electrons. In 1920 Rutherford, had suggested that there might be a neutral particle, possibly a proton and an electron tightly bound together, which he called a neutron.

Fig. 2 Plot of the exponential decay law. The number of radioactive nuclei at given time t is, $N(t) = N_0 e^{-\ln 2 t/T}$, where N_0 is the number of nuclei at $t = 0$ and T is the “half-life” for a specific radioactive nuclei and represents the period of time in which half of the nuclei of a particular radioactive element disintegrate. It can be observed that the initial number of nuclei N_0 reduces to $N_0/2$ after a time T ; after two half-lives $2T$, reduces to $N_0/4$; after three half-lives $3T$, it reduces to $N_0/8$, and so on.

The 1930s were considered the golden decade of physics and chemistry. Research groups all over the world were making new discoveries about fundamental properties of matter. Their findings were published almost month by month, sometimes by a difference of weeks or even days.

In 1930, in Berlin, W. Bothe and H. Becker performed several experiments bombarding light nuclei (beryllium, boron, lithium) with α -particles (${}^4\text{He}_2$) emitted from a radioactive polonium source (Bothe and Becker, 1930). They observed the production of a very penetrating electrically-neutral radiation that they thought to be very high energy γ -rays (photons). In the case of beryllium, the proposed nuclear reaction was ${}^9\text{Be}_4 + {}^4\text{He}_2 = {}^{13}\text{C}_6 + \gamma$.

Soon afterwards, in Paris, Frederick Joliot and his wife, Irene Curie, repeated these experiments using a much stronger polonium α source. They measured the absorption of the unknown γ -rays using sheets of lead, aluminum, carbon, etc., with different thicknesses and found that the radiation had more penetration power than estimated initially by Bothe. They found that 4.7 cm of lead were needed to reduce the intensity of the radiation by one-half. Calculating the absorption expected by Compton scattering process, they found the energy of the γ -rays from the bombardment of beryllium with α particles to be about 15 MeV. This was much higher than the energy of γ -rays emitted by naturally radioactive substances. However, the Joliot-Curies reached a similar conclusion to that obtained by the German team: the radiation produced was very high-energy γ -rays (Curie, 1931; Joliot, 1931).

Early in 1932, they performed new experiments bombarding beryllium with α particles. This time they found that placing a sheet of material such as paraffin, which contained hydrogen, between the “assumed” γ -rays and their ionization-chamber detector produced a secondary radiation that greatly increased the ionization in their detector. They correctly assumed that this secondary radiation had the ability to eject protons. By measuring the range of the protons on air, they found the energy of the protons to be 5.7 MeV. In order to eject a proton from a hydrogenated substance with such energy, the “assumed” γ -rays must be at least 50 MeV. This result was quite unexpected and clearly showed a contradiction on the γ -ray hypothesis for the emitted primary radiation. They promptly argued the possible existence of a new mode of interaction of radiation with matter (Curie and Joliot, 1932a,b).

Just after the publication of Curie and Joliot (1932a) on their new experimental results, English physicist James Chadwick reported them to Rutherford. Both were not convinced about Curie-Joliot’s conclusions. Immediately Chadwick decided to repeat the experiment at the Cavendish Laboratory in Cambridge.

Chadwick thought that it was unlikely that protons were ejected by Compton scattering, as proposed by Curie and Joliot. He put forward two arguments: it required γ -rays of very high-energy, and the number of protons observed was several times greater than predicted for this scattering process. Therefore, he decided to study the properties of the radiation produced when beryllium was bombarded by polonium α particles. He exposed many materials to this radiation, including gases of hydrogen, helium, oxygen, nitrogen, and argon.

Chadwick’s experiments showed that the beryllium radiation ejected particles of about the same number from all the gases. Considering the ionization power and range, the particles ejected from hydrogen behaved like protons with an energy of 5.7 MeV; this recoil energy of the hydrogen atoms required incident gamma-rays of about 50 MeV. In the case of nitrogen, 90-MeV gamma-rays were needed to produce the recoil of nitrogen atoms observed with energy of 1.4 MeV. It is important to note that gamma-rays from radioactive decay are in the energy range from a few keV to approximately 8 MeV.

After 10 days of intense work, in February 1932 Chadwick, in a letter published in Nature (Chadwick, 1932a), concluded that his experiments and the previous Joliot-Curies’ data proved the possible existence of the neutron, which Rutherford had proposed 12 years earlier. Chadwick pointed out in his communication: “These results were very difficult to explain on the assumption that the beryllium radiation was a quantum radiation, if energy and momentum are to be conserved in the collisions. The difficulties disappear, however, if it be assumed that the radiation consists of particles of mass 1 and charge 0, or neutrons.” Therefore, the reaction he proposed was ${}^9\text{Be}_4 + {}^4\text{He}_2 = {}^{12}\text{C}_6 + {}^1\text{n}_0$. A more detailed account of Chadwick’s experimental results and conclusions appeared in the Proceedings of the Royal Society on May 1932 (Chadwick, 1932b).

In 1935, James Chadwick received the Nobel Prize in physics for this work. After Chadwick’s neutron discovery, the idea that electrons were permanent constituents of nuclei was abandoned. Instead, the nucleus was assumed to contain N neutrons and Z protons, a total of $A = N + Z$ particles.

Carl Anderson—The positive electron or “positron”—August 1932

In 1930, there were only three known particles: the electron, the proton and the photon. The discovery of the neutron in 1932 was a bonus to physics and allowed scientists to advance in the knowledge of the atomic nucleus. That same year, Carl Anderson, an American physicist at Caltech, announced the discovery of a positively charged particle with the mass of the electron.

While Anderson was studying cosmic rays by taking photographs produced in a Wilson cloud chamber, he observed unexpectedly particle tracks. He visualized them by the steam condensed into fine droplets along the track of electrically charged particles crossing the chamber. A magnetic field produced by a coil bent the tracks, which allows determining the charge sign, positive or negative, of the particle. He found a number of tracks whose orientation suggested that they were caused by positively charged particles; however, these particles were too small in mass to be protons (Anderson, 1932a,b, 1933).

In August 1932, after many experiments and observations, Anderson determined that the tracks were “positrons,” particles with the same mass as the electron, but with opposite electrical charge.

Early in 1932, I. Curie and F. Joliot failed to discover the positron during certain experiments they performed a few months before Anderson’s discovery. By analyzing the cloud chamber photographs of the neutrons and γ -radiation produced in the reaction ${}^9\text{Be}_4 + {}^4\text{He}_2$, they observed “several Compton electrons which seemed indeed to behave strangely with respect to the direction of

the magnetic field." They reported that while some tracks could be ascribed to Compton electrons passing through the volume of the chamber, "several tracks, having the same appearance as the electron tracks, showed a curvature opposite to that of others" (Curie and Joliot, 1932c).

The positron had been conjectured in 1928 by Paul Dirac, an English theoretical physicist, who proposed that electrons might have a positive charge and negative energy. Although a new particle was not explicitly predicted, the solutions of the Dirac equation did allow electrons to have either positive or negative energy. However, the positrons were observed and understood by Anderson without taking into account Dirac's conjecture. Soon after the positron was considered as the "antiparticle" of the electron.

Carl D. Anderson received the Nobel Prize in Physics 1936 for the discovery of the positron. He shared the prize with Victor F. Hess who discovered cosmic radiation.

Irene Curie and Frederick Joliot—artificial radioactivity—1934

At the beginning of 1934, Irene Curie and Frederic Joliot published several articles in which they announced that they had artificially produced new radio-elements (Curie and Joliot, 1934a,b; Joliot and Curie, 1934a,b).

The Joliot-Curies showed that by bombarding various non-radioactive light elements (boron, magnesium, aluminum) with α -particles emitted by a polonium source, they could create new radioactive isotopes. They observed that the irradiated material remained radioactive during a reasonable (long) period after the end of the bombardment. They also found that the new created radioisotopes emitted positrons in the case of aluminum and boron, while positrons and electrons were emitted in the case of magnesium.

In their experiments, the Joliot-Curies came across simultaneously two phenomena: one, it is possible to produce radioactive nuclei artificially, and two, the product of some nuclear-reaction decays emit a positron (e^+ , an antielectron), or an electron (e^-), now called β^+ or β^- decays.

They suggested that the phenomenon takes place in two stages. First, the capture of the α -particle and the instantaneous expulsion of a neutron, with the formation of an unstable radioactive nucleus. Second, the unstable nucleus decays transmuting into a stable nucleus.

In the case of the bombardment of a sheet of aluminum by α particles, a new radioactive nucleus, which they called "radio-phosphorus," was created; instantaneously, a neutron was ejected, and the remaining unstable nucleus decayed exponentially with a half-life of about 3 min emitting a positron and a positron.

The transmutation reaction was $^{27}\text{Al}_{13} + ^4\text{He}_2 \rightarrow ^{30}\text{P}_{15} + ^1\text{n}_0$. The new radioactive nucleus created was $^{30}\text{P}_{15}$, which was disintegrated by emitting positrons (e^+) and a neutrino (ν), giving a stable nucleus $^{30}\text{Si}_{14}$. In a formula, it can be written as, $^{30}\text{P}_{15} \rightarrow ^{30}\text{Si}_{14} + e^+ + \nu$.

The existence of neutrinos was proposed by Wolfgang Pauli in 1930, in a letter to the participants of a physics conference in Tuebingen, Germany. He suggested that a third particle might be emitted in β decay in order to explain the apparent non-conservation of energy after the emission of an electron (or positron) from an atomic nucleus.

Similarly, the Joliot-Curies interpreted the production of radioactive elements in the bombardment of B and Mg. In case of boron, the nuclear reaction was $^{10}\text{B}_5 + ^4\text{He}_2 \rightarrow ^{13}\text{N}_7 + ^1\text{n}_0$. The new radioactive nucleus was $^{13}\text{N}_7$, which disintegrated with emission of positrons and a neutrino with a half-life of 14 min, giving rise to a stable nucleus $^{13}\text{C}_6$. Therefore, the corresponding formula can be written as, $^{13}\text{N}_7 \rightarrow ^{13}\text{C}_6 + e^+ + \nu$.

The energy spectrum of the emitted positrons measured in the Joliot-Curies' experiment had a continuous form, similar to the β -ray spectrum, which perhaps, it might be attributed to the simultaneous emission of a neutrino in order to satisfy the principle of the conservation of energy and of angular momentum in the transmutation. The maximum energy of the measured positron spectrum was of the order of 1.5×10^6 eV for boron and 3×10^6 eV for aluminum. The radioactive elements formed during the irradiation were chemically separated from boron and aluminum, which as expected, had the chemical properties of nitrogen and phosphorus, respectively.

The Joliot-Curies were not able to observe similar effects when they used α -particles to bombard hydrogen, lithium, beryllium, carbon, nitrogen, oxygen, fluorine, sodium, silicon, or phosphorus. They ascribed this result, at least for some cases, to the too short half-lives of the products which made them impossible to be observed.

In their publications, the Joliot-Curies also suggested that radioactive elements might be produced "in different nuclear reactions with other bombarding particles: protons, neutrons, deuterons, neutrons."

Irene Curie and Frederic Joliot won the Nobel Prize of Chemistry in 1935, in recognition of their synthesis of new radioactive element.

The discovery of artificial radioactivity was fundamental for nuclear science and an important fact for the entire world. It brought the attention and inspired scientists all over the world to the possible use of different approaches to produce unknown radio-elements.

In Rome, Enrico Fermi had the idea to produce new radioactive elements by using neutrons, a particle electrically neutral, discovered 2 years earlier. He thought that neutrons might be more effective to make artificial radioactivity since they would not be repelled by the positive charge nuclei of the bombarded target atoms. However, the process could be more complicated because the neutrons were not produced spontaneously.

In June 1934, Fermi and his group from the University of Rome were able to discover more than 20 new radioactive isotopes using this method of neutron-induced nuclear reactions (Fermi, 1934; Fermi et al., 1934a,b).

They also made another important discovery. They proved that by decreasing the neutron energy (slowing down the neutrons) before they hit the target atoms, the production of new radioactive isotopes was more effective than using energetic neutrons, so called fast neutrons.

The cross-section of neutron absorption in nuclei largely increases when neutron velocity decreases. Slow neutrons turned out to be important in another phenomenon: induced nuclear fission, the discovery of which was a major event in the middle of the twentieth century.

Fission is a decay process that occurs when natural uranium nuclei (^{235}U , ^{238}U) are bombarded with slow neutrons and they break apart into two smaller, lighter nuclei. In 1938, the first induced fission was discovered by the German physicists Otto Hahn, Fritz Strassmann, and Lise Meitner (Hahn et al., 1937; Meitner et al., 1937). Spontaneous fission in ^{238}U was discovered in 1941 by Russian physicists Georgy Flyorov and Konstantin Petrzhak. It was difficult to distinguish between induced and spontaneous fission events because cosmic rays produce some neutrons,

Quantization

In physics, the term *quantization* refers to a process of transition from the domain in which classical laws apply, to the domain (often atomic or subatomic) in which it is necessary to apply the principles of quantum mechanics. More broadly, it refers to the necessity to take into account the discontinuity or graininess of certain variables. For example, a satellite can be placed into Earth orbit in any desired circular or elliptical path, but for an electron in an atom only certain orbits are allowed. In quantization of the electromagnetic field, the continuity of a wave-based description is replaced by the discontinuity of discrete particle-like quanta called *photons*.

Quantization of electric charge

In the 1800s, experiments with electric phenomena involved the transfer of large quantities of charge, such as in electric currents in circuits, so the question of the existence of a fundamental unit of charge did not arise. The first indication of a discrete unit of charge was revealed in the experiments of J. J. Thomson (1856–1940) at Cambridge University, in England.

Thomson's research was mainly focused on the properties of cathode rays, mysterious rays in gas discharge tubes (evacuated glass tubes containing two electrodes, one positive and the other negative). The rays appeared to leave the negative terminal (the cathode) and travel toward the positive terminal (the anode). In 1897, Thomson was able to deflect the rays in electric and magnetic fields, thus showing that they were particles, and he measured the ratio of their charge and mass. Thomson maintained that the particles, which he called *corpuscles* but are now known as *electrons*, were constituents of atoms and were released from the atoms of the small amount of residual gas in his discharge tubes.

More definitive evidence for the quantization of electric charge came in 1909 with the experiments of Robert Millikan (1868–1953) at the University of Chicago. By suspending oil droplets having just a few electric charges in an electric field, Millikan was able to measure the amount of charge on the drops. He observed that the charges were always small integer multiples of a quantity that he took to be the basic unit of charge. That basic unit of charge is now set at exactly the value $e = 1.602176634 \times 10^{-19}$ coulomb. All observed atomic, nuclear, and subnuclear particles have electric charges q that are small integer multiples of this basic unit of charge: $q = \pm ne$. Some theories have postulated the existence of fractional electric charges, and experiments with subatomic particles have been consistent with the predictions of these theories, but no isolated particles with fractional charges have so far been observed.

Quantization of energy

Although the 19th century had seen many successes in understanding the physical universe, particularly the development of the laws of electromagnetism and thermodynamics, a few unsolved problems remained. One in particular was the spectrum of *thermal radiation*, electromagnetic radiation (often in the infrared and visible regions) emitted by all objects because of their temperature T . This failure was especially troubling, because it suggested the inadequacy of the two great triumphs of 19th century physics, electromagnetism and thermodynamics.

The intensity of thermal radiation falls to zero at both large and small wavelengths, and it reaches a peak in between (Fig. 1). The result obtained from classical theory, called the *Rayleigh-Jeans formula*, approaches the data points at large wavelengths but fails completely at small wavelengths, where it predicts infinite radiation intensity:

$$I(\lambda) = \frac{2\pi c}{\lambda^4} kT \quad (1)$$

Fig. 1 The data points represent measurements of the spectrum of thermal radiation, which the classical theory cannot explain but which are fit perfectly by Planck's quantum theory.

where λ is the wavelength of the radiation, c is the speed of light, and k is the Boltzmann constant. The radiation intensity is defined so that $I(\lambda)d\lambda$ is the radiant power per unit area (measured, for example, in watts/m²) in the small wavelength interval $d\lambda$, such as might be absorbed by a suitable detector in the path of the radiation that is sensitive to wavelengths between λ and $\lambda + d\lambda$.

The solution to this dilemma was found in 1900 by Max Planck (1858–1947), working at the University of Berlin, in Germany. Planck analyzed theoretically the thermal radiation in a hollow metal box with the walls at temperature T . The radiation filled the inside of the box and could escape through a small hole in one of the walls. Planck considered the process by which the oscillating atoms in the walls of the box absorb and re-emit the reflected radiation. Clearly Planck had to find a way to suppress the intensity of short-wavelength (high-frequency) radiation that caused the failure of the classical theory.

He accomplished this by postulating that the atoms could absorb and re-emit radiation in discrete bundles that were integer multiples n of a basic quantity of energy ϵ . This basic quantity (or *quantum*) of energy was in turn determined by the frequency of the oscillating atoms (which was assumed to be the same as the frequency f of the radiation), so that $\epsilon = hf$, where h is the constant of proportionality between the energy and frequency, now known as *Planck's constant*. Thus Planck's quantization assumption is $E = n\epsilon = nhf$. An oscillating atom in the walls of the cavity can have 2 types of energy (kinetic and potential), and from statistical mechanics we learn that the average value of each form of energy of an atom at temperature T is $kT/2$. So on the average, the thermal energy kT of the atoms is not sufficient to provide an energy of hf at high frequency, and thus the short-wavelength (high-frequency) radiation is suppressed. With this assumption, Planck was able to derive an expression for the radiation intensity:

$$I(\lambda) = \frac{2\pi hc^2}{\lambda^5} \frac{1}{e^{hc/\lambda kT} - 1} \quad (2)$$

Planck's function fits the data perfectly, as shown in Fig. 1.

Five years later, in 1905, Albert Einstein (1879–1955) extended Planck's quantization ideas to the radiation itself, asserting that the radiation could be considered as composed of *light quanta*, now known as photons. On that basis, Einstein derived equations for the photoelectric effect, and in 1915 Millikan's experiments confirmed Einstein's theory.

Rutherford scattering and the nuclear atom

In 1895, Ernest Rutherford (1871–1937) traveled from New Zealand, where he earned his undergraduate physics degree, to the Cavendish Laboratory at Cambridge University in England to continue his physics education. There he worked under the supervision of J. J. Thomson. At first, Rutherford's research involved the transmission and detection of radio waves, a continuation of the investigations he had begun as an undergraduate in New Zealand. At one point Rutherford had the record for the largest distance over which radio waves could be transmitted and received.

The discovery of X rays in 1895 by Wilhelm Röntgen (1845–1923), in Germany, provided a new dimension to the research of Thomson and Rutherford. They set out to measure the conduction of electricity by various gases exposed to X rays (then known as Röntgen rays). Their hypothesized explanation for the effect, that the X rays removed electrons from neutral atoms, thereby changing them into charged ions, turned out to be correct. Rutherford published three papers describing these experiments, one jointly with Thomson in 1896 and two in 1897 under Rutherford's sole authorship.

Yet another dimension to the research arose in 1896 with the discovery of radiation emanating from uranium and its compounds by the Frenchman Henri Becquerel (1852–1908). In his second paper of 1897, in which he measured the speeds of the gas ions, Rutherford concluded:

Further experiments, which are not yet completed, have been made to find the velocity of the ions of a gas conducting under the influence of the radiation given out by uranium and its salts. It can be shown that the velocity of the ions in the conducting gas is the same as when the gas is acted on by Röntgen radiation, so that the carrier in the two cases is identical. Further results, however, must be reserved for a future paper. (Rutherford, 1897).

As promised, 2 years later Rutherford would produce the more detailed work on the effect of uranium radiation on electrical conduction by gases. Although he published several more papers on this subject, it is obvious from these papers that his interest was shifting from the effects of this radiation on gases to the origin and properties of the radiation itself.

In 1898, Rutherford left Cambridge to become Professor of Physics at McGill University in Montreal, Canada. He would remain there for 9 years, during which he published 70 papers on the subject of uranium radiation, or *radioactivity* as it soon came to be known. The research described in these publications included the sequence of elements produced in the radioactive decays of uranium and thorium and the chemical extraction and identification of the various decay products (research for which he would be awarded the 1908 Nobel Prize in Chemistry), as well as the nature of the alpha, beta, and gamma radiations emitted in the decays. Most of his publications in his last year in Canada (1906–07) concerned the nature of the alpha particle. In one experiment in particular (Rutherford, 1906), he obtained a photographic image of the pattern of alpha particles emitted by a source on a wire as they passed through a narrow slit. By covering half of the slit with a thin layer (0.003 cm) of mica, he could observe the amount of scattering of the beam due to the mica. His result is shown in Fig. 2, in which the bottom half of the image shows the more diffuse result of passing through the mica. Rutherford estimated that the average deviation of the beam was about 2° , and he concluded:

...it can easily be calculated that the change in direction of motion of some of the α particles in passing through the thickness of mica (0.003 cm) would require over that distance an average transverse electric field of about 100 million volts per cm. Such a result brings out clearly that the atoms of matter must be the seat of very intense electrical forces—a deduction in harmony with the electronic theory of matter.

In 1907, Rutherford returned to England as Professor and Chair of Physics at the University of Manchester, the personally hand-picked successor to the retiring Physics Chair, Arthur Schuster. Arriving in Manchester somewhat unexpectedly during a school holiday, he found the physics laboratory deserted except for a young German postdoctoral researcher, Hans Geiger (1882–1945), who had arrived the year before to work with Schuster after completing his doctoral degree in 1906 in Erlangen, Germany. Geiger's year at Manchester had not been particularly successful (only one minor paper published), and he was set to return to Germany to continue working in the area of his doctoral research, the passage of high currents through gases in discharge tubes. Geiger showed Rutherford around the laboratory, and Rutherford was so impressed with the young German that he asked him to stay on as his assistant. Despite having no background or experience in research with radioactivity, Geiger accepted and remained at Manchester for a total of 5 years, eventually becoming recognized as one of the world's leading experts on radioactivity.

Rutherford first assigned Geiger to obtain a more quantitative result for the diffuse scattering of α particles. Geiger designed an apparatus that allowed the α particles to travel through an evacuated tube (thus eliminating scattering by air), pass through a narrow slit (that could be covered by a foil), and then strike a fluorescent screen, on which Geiger could observe the flashes of light (scintillations) caused by the impact of individual particles and count them with a microscope. Fig. 3 shows Geiger's results for 0, 1, and 2 gold foils covering the slit. Geiger concluded that the average scattering angle for one gold foil was about 0.2° (Geiger, 1908).

Fig. 2 Rutherford's alpha-particle scattering results, in which the particles pass through a narrow slit whose bottom half is covered by a thin layer of mica (Rutherford, 1906).

Fig. 3 Geiger's alpha-particle scattering results. (Data from Geiger, 1908).

Now working with undergraduate student Ernest Marsden, Geiger next used a similar arrangement with a scintillator and microscope to try to detect α particles reflected from foils, that is, scattered at angles greater than 90° . They concluded that about 1 particle in 8000 is reflected from the foil (Geiger and Marsden, 1909). Later Rutherford would recall upon hearing of their result:

It was quite the most incredible event that ever happened to me in my life. It was almost as incredible as if you fired a 15-inch shell at a piece of tissue paper and it came back and hit you (Rutherford, 1938).

Why was Rutherford so surprised at this result? Based on the prevailing model of the structure of the atom as a diffuse ball of positive charge in which the negative electrons were embedded (proposed by J. J. Thomson and known as the *Thomson model* of the atom), large scattering angles were expected only from multiple scatterings. If each scattering resulted in a deflection of about 0.2° (the average scattering angle) as Geiger had previously found, then a scattering angle of 90° would require at least 450 consecutive scatterings, *all in the same direction*. In its passage through the foil, the α particle is expected to strike atoms randomly and thus scatter with equal probability to the left or to the right, so such a result would be somewhat like tossing a coin 450 times and having it come up heads every time, which would have a probability of about 1 in 10^{135} . This enormous difference between the expected probability for backscattering (1 in 10^{135}) and the observed probability (1 in 8000) is what shocked Rutherford.

Later Geiger would recall:

One day (in 1911) Rutherford, obviously in high spirits, came to my room and told me he now knew what the atom looked like and how to explain the large deflections of the alpha particles. On the very same day I began an experiment to test the relation expected by Rutherford between the number of scattered particles and the angle of scattering (Eve, 1939).

Rutherford proposed that the mass and positive charge of the atom were not diffused throughout its volume, as in the model proposed by J. J. Thomson, but instead are concentrated in a tiny region at its center – the atomic nucleus. The large-angle deflections in this interpretation were then simply the result of an alpha particle encountering an object more massive than itself. Each scattering would then be the result of a single encounter, rather than of a succession of encounters. Based on this concept, Rutherford derived an expression for the number of scattered particles that would appear at a scattering angle ϕ :

$$N = \frac{(kze^2)^2 ntI}{4r^2 m^2 V^4 \sin^4 \phi / 2} \quad (3)$$

where k is the electronic constant (sometimes written as $1/4\pi\epsilon_0$), ze is the electric charge of the α particle, Ze is the electric charge of the nucleus, n is the density of atoms in the scattering foil, t is the thickness of the scattering foil, I is the intensity of the incident beam of α particles, r is the distance of the detectors from the scattering foil, and m and V are the mass and speed of the α particle. (Rutherford, 1911)

If Rutherford's hypothesis were correct, then the scattering should depend on (1) the square of the atomic number Z of the scattering material, (2) the thickness of the foil, (3) the speed of the α particles, and (4) the scattering angle. Geiger and Marsden set out to test all four of these dependences in a detailed series of experiments. (Because the concept of atomic number had not yet been developed, Geiger and Marsden did the test in terms of atomic weight instead.) Two sets of their results are shown in Fig. 4 (Geiger and Marsden, 1913). In Fig. 4A, the dependence of the scattering rate on the foil thickness is shown. This dependence is a critical test of the nuclear model, because according to Thomson's model the scattering should depend on the foil thickness as $t^{1/2}$, but Fig. 4 clearly shows the linear dependence on t as predicted by Rutherford's formula. This dependence serves clearly to differentiate

Fig. 4 Geiger and Marsden results for alpha scattering. (A) Thin foils of gold, silver, copper, and aluminum all show a linear dependence on the thickness. (B) The scattering probability as a function of scattering angle is perfectly fit by Rutherford's theory. (Data from Geiger and Marsden, 1913).

scattering by a single event (t dependence, as in Rutherford's model) from scattering from multiple events ($t^{1/2}$ dependence, as in Thomson's model). Fig. 4B shows the dependence on the scattering angle. Rutherford's formula, with the dependence of $\sin^{-4}(\phi/2)$, fits the data perfectly and constitutes a great triumph for Rutherford's idea and calculation, as well as for the careful and precise experiments of Geiger and Marsden.

Atomic energy levels and the Bohr model

The idea that matter was composed of atoms is an ancient abstraction, but it was given substance in the 1800s by English chemist John Dalton (1766–1844), who suggested that atoms of various elements could combine in definite proportions to form chemical compounds. The impetus for a physical model of atomic structure was engendered by the previously mentioned discoveries of the 1890s: the electron by Thomson, in 1897, and radioactive decay by Becquerel, in 1896. Electrons, including those observed as cathode rays in discharge tubes as well as those released from metallic surfaces illuminated by visible and ultraviolet radiation (the photoelectric effect), presumably did not arise spontaneously but were instead constituents of atoms ripped loose by electric fields, thus putting an end to the 19th-century idea of atoms as *indivisible*. Rutherford's research showed that in radioactive decay one type of atom would transform into another, ending the idea of the atom as *immutable*. It then became possible to imagine the existence of a physical model for the internal structure of atoms.

Although it was believed that electrons were constituents of atoms, the number of electrons in the atom was far from clear. Being electrically neutral, atoms must contain equal quantities of positive and negative charge, but the nature of the positive charge was unknown. Moreover, it was well known from classic electromagnetic theory that an assembly of positive and negative charges at rest could not achieve mechanical equilibrium. As a result, early models put the electrons in motion around or through the positive charge, but this led to another problem: as with all accelerated charges, the orbiting electrons would radiate electromagnetic energy, resulting in the collapse of the structure.

In the late 19th and early 20th century, atomic spectroscopists studied the light and other radiations emitted by atoms, for example when a vapor of an element is heated or when an electric current passes through the vapor. In the process they identified many hundreds and occasionally thousands of spectral lines from individual elements in the visible and near visible (ultraviolet, infrared) regions of the spectrum. Using equipment such as precisely ruled diffraction gratings, the wavelengths of these spectral lines had been accurately measured, often to a precision of less than 1 part in 10^4 . The early atomic model builders faced a challenge in accounting for the many different wavelengths or frequencies of the emitted radiations. It was initially assumed that each individual frequency was associated with an electron oscillating about its equilibrium position, suggesting that to account for the multitude of spectral lines there were many hundreds or even thousands of electrons in each atom.

An early model due to Thomson proposed that the electrons moved without resistance in an atom-sized sphere of massless positive charge. All of the mass of the atoms resided in the electrons, which must then number around $2000A$ for an atom of mass number A (an integer closest to the mass of the atom in atomic mass units, now known to be the total number of protons and neutrons in the nucleus). Soon scattering experiments showed that the number of electrons was instead of order A , which indicated that most of the mass of the atom must reside in the sphere of positive charge of unknown character. Rutherford's 1911 theory and the 1913 experiments of Geiger and Marsden showed that the positive charge was not diffuse but instead was concentrated at the center of the atom in a nucleus of diameter 10^{-5} times that of the atom.

Somewhat surprisingly, Rutherford's revelation did not lead to an immediate flurry of new atomic models based on the nuclear atom. Instead, the task fell to a young Danish visitor to Rutherford's Manchester lab in 1912, Niels Bohr (1885–1962). Bohr had finished his doctorate degree in physics at the University of Copenhagen in 1911; his dissertation (written in Danish) dealt with the theoretical analysis of the behavior of electrons in metals. With funding for postdoctoral study, Bohr chose to work at Cambridge

University with Thomson, who Bohr felt would help him advance his theoretical research into the properties of electrons. Bohr had produced an English translation of his dissertation, which he hoped Thomson would read. However, Thomson seemed indifferent to Bohr's research and the two never forged an effective working relationship. In December 1911, Bohr attended a talk in Cambridge given by Rutherford, and Bohr was so impressed with Rutherford's research on radioactivity that he arranged to leave Cambridge in March 1912 to spend the rest of his postdoctoral year in Rutherford's lab in Manchester. Bohr's goal at that time was to acquire some experimental proficiency in the field of radioactive decay. To that end, he participated in a laboratory practicum on radioactivity that Hans Geiger had developed as training for new students who wanted to undertake advanced research with Rutherford.

Bohr completed the radioactivity practicum in May 1912 and while waiting for radioactive material for the project he was assigned by Rutherford, he continued to work on his electron theory of metals. But within about 2 months he turned his attention to a topic that was more in line with the main thrust of the research at Manchester: the internal structure of the atom. His first project was a theoretical analysis of the passage of charged particles (alpha and beta particles from radioactive decays) through matter, in particular the effect of the bound electrons in atoms. He completed the analysis in August of 1912. Among his conclusions were that the H_2 molecule contained two electrons (thus one electron in the H atom) and the He atom contained two electrons. The number of electrons in an atom was at that time not well established, so this was the first step into Bohr's insight into the structure of the atom (Bohr, 1913a). He also tried to determine the number of electrons in more massive atoms, but the results had large uncertainties due to the then-current accepted values of the basic physical constants.

Bohr returned to Copenhagen in September 1912 and continued to work on the theoretical analysis of the structure of atoms. He published his results in a series of three papers in the *Philosophical Magazine* (Bohr, 1913b, c, d). The first of those papers discussed his model for the structure of atomic hydrogen. He began with a planetary structure, with a single electron (charge $-e$) in a circular orbit of radius a about a nucleus (according to Rutherford's model) of charge $+e$. (Other planetary models had been tried previously without success; they were based on a multitude of electrons circulating in a series of coplanar rings, like the planet Saturn.) Setting the electric force¹ e^2/a^2 equal to the centripetal force $ma\omega^2 = mv^2/a$ yields an expression for the orbital kinetic energy, $K = \frac{1}{2}mv^2 = e^2/2a$. (Here m is the electron's mass, ω its angular speed, and v its tangential speed around the circular orbit.) Combining with the potential energy $U = -e^2/a$ gives the total mechanical energy of the electron $E = K + U = -e^2/2a$. The negative value of E suggests a bound system, with binding energy (the energy necessary to remove the electron from the atom) $W = -E$. Manipulating these expressions, Bohr obtained two equations for the orbital parameters – the frequency f and the diameter $2a$:

$$f = \frac{\omega}{2\pi} = \frac{W^{3/2}\sqrt{2}}{\pi e^2\sqrt{m}} \quad (4)$$

$$2a = \frac{e^2}{W} \quad (5)$$

This orbital motion has mechanical stability, but the circulating electron would still radiate electromagnetic energy. Bohr avoided this problem by postulating that the electron could exist in special *stationary states* without radiating.

These two equations contain three unknowns: the orbital frequency f , radius a , and binding energy W , so it is not possible to solve for the values of all three parameters. Bohr needed another relationship among the parameters. For the missing ingredient, he applied the quantization condition $E = nhf$ invented by Max Planck in 1900 in his analysis of thermal radiation. Following Planck's lead, Bohr proposed that the binding energy could be expressed as $W = cnhf$, where c is a numerical factor of order unity. Bohr guessed at the value $c = 0.5$ by taking the average between the fully bound electron (binding energy = W) and the unbound electron (binding energy = 0). Subsequently he developed a more rigorous derivation that remarkably agreed with his guess.

Bohr's great insight was to marry the classical physics that gave Eqs. (4), (5) with the Planck-Einstein quantum theory, thereby producing the first quantum theory of atomic structure. Combining his quantum equation with the classical equations he obtained one equation for each of the three parameters:

$$W_n = \frac{2\pi^2 me^4}{n^2 h^2} \quad (6)$$

$$f_n = \frac{4\pi^2 me^4}{n^3 h^3} \quad (7)$$

$$2a_n = \frac{n^2 h^2}{2\pi^2 me^2} \quad (8)$$

The subscript n on each value indicates that the parameter takes different values for each value of the index n . Bohr assumed that the largest value of W would give the most stable state of the atom, so he put $n = 1$ and used the then-current values of e , m , and h to calculate $W_1 = 13$ electron-volts, $f_1 = 6.2 \times 10^{15}$ Hz, and $2a_1 = 1.1 \times 10^{-8}$ cm; he concluded that these were of the correct order of magnitude as ionization potentials, optical frequencies, and atomic sizes.

¹The notation adopted here follows as closely as possible that of Bohr's paper, in particular using cgs units for electromagnetic quantities. At the conclusion the switch to SI units can be made by replacing e^2 with $e^2/4\pi\epsilon_0$.

The problem remained to calculate the frequencies or wavelengths of the radiations emitted by atomic hydrogen. The frequencies of the orbital motion did not agree with those of the observed radiations. Bohr puzzled over this problem, but as soon as one of his colleagues made him aware of the Balmer series for the emitted radiations from hydrogen, it suddenly became clear to him. Johann Balmer (1825–98) was a Swiss mathematician who had (by trial and error) in 1885 discovered a numerical relationship for a set of frequencies in the visible and ultraviolet radiations emitted by hydrogen:

$$f_R = f_0 \left(\frac{1}{4} - \frac{1}{n^2} \right) \quad (9)$$

where $f_0 = 3.29 \times 10^{15}$ Hz and $n = 3, 4, 5, \dots$. Here f_R indicates the frequencies of the emitted radiation, as distinguished from the orbital frequencies f_n .

Balmer's formula led Bohr to two insights: (1) It was no accident that the binding energies W_n and the radiant frequencies f_R both depended on the index n as n^{-2} . The binding energies and emitted frequencies must be related to one another. (2) The minus sign in Eq. (9) suggests that the frequencies depend on the *difference* of two binding energies. Bohr proposed that the energy difference $W_{n_2} - W_{n_1}$ in passing from a state with $n = n_1$ to a state with $n = n_2$ appears as the energy hf_R of the emitted radiation, so that

$$f_R = \frac{W_{n_2} - W_{n_1}}{h} = \frac{2\pi^2 me^4}{h^3} \left(\frac{1}{n_2^2} - \frac{1}{n_1^2} \right) \quad (10)$$

Clearly putting $n_2 = 2$ gives the frequencies of the Balmer series, and Bohr calculated the value of the quantity outside the parentheses in Eq. (10) to be 3.1×10^{15} Hz, which agrees with Balmer's value within the then-current uncertainties of Planck's constant and the electron mass and charge. Putting $n_2 = 3$ reproduces the values of a series of radiations in the infrared region, called the Paschen series, and Bohr predicted the frequencies of the then-undiscovered series of radiations with $n_2 = 1, 4$, and 5, which turned out to agree with his formula once measured values were available. Moreover, a similar set of spectral lines observed in stars was soon shown to follow Bohr's theory for ionized helium (He^+), which also contains a single electron. In the case of He^+ , the electron is circulating about a nucleus with a charge of $2e$, and the change in the electric force equation introduces a factor of 4 into Eq. (10). The perfect agreement with the frequencies of the H and He spectral lines was a great triumph for Bohr's theory (Bohr, 1913e).

In summary, Bohr's theory for hydrogen represents the atom by a series of discrete levels (stationary states), in which the electron can circulate without radiating. Radiation is emitted only when the electron makes a transition from one state to another. The energy of the radiation is equal to the difference in energy of the initial and final states. Fig. 5 shows some of the electron states in atomic hydrogen and some of the emitted radiations. In more modern terminology, the energy levels are said to be *quantized*, and the energy difference appears as the energy of an emitted photon or quantum of radiation.

Additional confirmation of the idea of discrete states in atoms came within a year of Bohr's publication. In Germany, James Franck and Gustav Hertz carried out an experiment in which they passed a beam of electrons through mercury (Hg) vapor (Franck and Hertz, 1914). When the electron beam was accelerated through 4.9 V, the electron current suddenly dropped. Franck and Hertz interpreted this as evidence that the electrons in the beam were losing energy by colliding with Hg atoms and in the process driving the atoms from their ground state to an excited state known to exist at 4.9 eV. This energy difference corresponds exactly to an ultraviolet radiation emission in Hg of wavelength 254 nm. Although Bohr's theory was not able to calculate the excited states in a many-electron atom like Hg, the notion of radiation emission between discrete energy states was consistent with Bohr's ideas.

Fig. 5 Some energy levels in atomic hydrogen and their emitted radiations. All energies are given in units of eV.

For his discoveries, Bohr was awarded the 1922 Nobel Prize in physics. He was honored in particular for “his services in the investigation of the structure of atoms and of the radiation emanating from them.”

Bohr also was able to obtain a more rigorous justification for the factor $c = 0.5$ that he used in adapting Planck’s formula to the structure of hydrogen. Bohr’s guess amounted to taking the mean or average value between the energy of the unbound electron (zero) and the fully bound one. Instead, Bohr compared (for arbitrary value of c) the orbital frequency of the electron, as in Eq. (7):

$$f_n = \frac{\pi^2 m e^4}{2c^3 n^3 h^3} \quad (11)$$

with the frequency of the emitted radiation for a transition from a state n to state $n-1$:

$$f_R = \frac{\pi^2 m e^4}{2c^2 h^3} \left(\frac{1}{(n-1)^2} - \frac{1}{n^2} \right) \approx \frac{\pi^2 m e^4}{c^2 n^3 h^3} \quad (12)$$

where the last result is an approximation for large values of n . Bohr asserted that in the classical limit of the quantum atom, the atom will radiate at the orbital frequency, so the limit of the quantum frequency must match the orbital frequency. Comparing Eqs. (11) and (12) immediately gives $c = 0.5$. This agreement of classical and quantum physics in the intermediate range is known as the *correspondence principle*.

In developing his model, Bohr introduced not only the frequency condition (Eq. 7) but also the fundamental quantum ideas of the correspondence principle and nonradiating stationary states. It would be another decade before the formal mathematical basis of quantum mechanics was established (Schrödinger, 1926), incorporating these ideas. The full calculation reproduces Bohr’s energy levels but eliminates such classical concepts as orbits in fixed planes, and answers an objection raised by Rutherford in response to Bohr’s theory: how does the electron know beforehand which state it is going to jump to? The quantum calculation gives a set of probabilities to reach any final state from any initial state.

Although Bohr also tried to calculate the orbits for electrons in atoms with more than one electron, in his 1913 papers he did not have available the methods of quantum mechanics that a dozen years later would provide the tools necessary to analyze more complex atoms. Nevertheless, the rules he provided, and especially the idea that the emitted radiations corresponded to electron transitions between stationary states, would provide the keys to understanding the structure of atoms.

Quantization of angular momentum

The classical angular momentum of a particle of mass m moving in a circular orbit of radius r with tangential speed v is a vector $\mathbf{L}$ perpendicular to the plane of the orbit and of length $|\mathbf{L}| = mvr$. Taking the velocity from the kinetic energy (Eq. 6) and the radius from Eq. (8) gives

$$|\mathbf{L}| = mvr = m \left(\frac{2\pi e^2}{nh} \right) \left(\frac{n^2 h^2}{4\pi^2 m e^2} \right) = n \frac{h}{2\pi} \quad (13)$$

As Bohr states in his paper (Bohr, 1913b), “...the angular momentum of every electron round the center of its orbit will in the permanent state of the system be equal to $h/2\pi$...”. By “permanent state,” Bohr means lowest energy state, corresponding to $n = 1$ in Eq. (13).

Eq. (13) indicates that the orbital angular momentum cannot take any arbitrary value, but is restricted to the set of values $nh/2\pi$. In analogy with the quantization of energy and electric charge, this is known as the *quantization of angular momentum*. The full quantum mechanical calculation preserves this principle but gives a very different set of values – the length of the angular momentum vector is

$$|\mathbf{L}| = \sqrt{l(l+1)} \frac{h}{2\pi} \quad (14)$$

where $l = 0, 1, 2, \dots$. Note that in the lowest energy state, the quantum result is $|\mathbf{L}| = 0$, while in Bohr’s calculation, $|\mathbf{L}| = h/2\pi$. Moreover, in the quantum calculation the components of the vector $\mathbf{L}$ along any particular axis are limited to the values $mh/2\pi$, where m is an integer ranging from $-l$ to $+l$. That is, the vector $\mathbf{L}$ can take only certain directions in space corresponding to the allowed components on the chosen axis. This property is known as *spatial quantization*.

Quantized energy levels in nuclei

The acceptance of Bohr’s theory of atomic structure was enhanced by the excellent agreement between the energy levels he calculated from his planetary model and the extremely precise values of the energies of the emitted radiation quanta (photons) determined from the wavelengths of the emitted radiations measured by atomic spectroscopy. Unfortunately, attempts to carry over the methods to the structure of nuclei in the 1920s were hampered by the lack of a theory to calculate the expected energy levels of nuclei and the rather poor ability to measure the energies of the emitted photons (nuclear γ rays).

Fig. 6 Transition energies determined from internal conversion (Rutherford et al., 1930), shown in blue, compared with the presently accepted levels of ^{214}Bi . All energies are given in units of keV.

The situation was rescued somewhat by the existence of a competing process to γ -ray emission in nuclei, namely *internal conversion*. In γ -ray emission, the nucleus makes a transition from an initial energy level E_i to a final energy level E_f and emits a γ -ray photon whose energy hf satisfies the Bohr frequency condition $hf = E_i - E_f$. In internal conversion, the available transition energy $E_i - E_f$ instead ejects one of the atomic electrons. The kinetic energy K_e of the emitted electron is equal to the available transition energy less the energy cost to free a bound electron from the atom, the electron binding energy B_e , so that $K_e = (E_i - E_f) - B_e$. Values of the electron binding energies were already known in the 1920s, so by doing precise measurements of the kinetic energies of the emitted internal conversion electrons (for example, using a magnetic spectrometer) it was possible to deduce the nuclear energy levels.

Although using present-day equipment the energies of γ -ray photons can be measured to a precision often below 1 part in 10^4 , thus enabling equivalently precise conclusions about the energy levels in nuclei, in the 1920s the precision of electron energy measurements far exceeded that of γ -ray photons, and thus internal conversion often provided the key to understanding nuclear energy states.

For example, consider the energy levels of the nucleus ^{214}Bi populated in the radioactive β decay of ^{214}Pb (known as radium B).² Measurements of the internal conversion electrons revealed the following energy differences of the nuclear states (energies in keV): 53, 243, 260, 297, 354, with uncertainties of typically a few parts in 10^3 . (Rutherford et al., 1930) Knowing only the differences in energy of the nuclear states does not permit the ordering of the states to be deduced, but modern measurements led to the currently accepted energy levels of ^{214}Bi shown in Fig. 6. Note how well the early measurements of the transition energies match the accepted energy levels.

An alternative approach to studying quantum states in nuclei is to observe the α decays of radioactive species. High-resolution observations of the α particles from particular decays showed several different energies from the same decay process (called the *fine structure* of α decay). These were interpreted by Gamow (1930, 1937) in the case of the decay of ^{212}Bi (known as ThC) to ^{208}Tl as decays from the parent nucleus to different energy levels in the daughter, which could be verified by also studying the same energy levels by internal conversion. If the hypothesis were correct, the energy level differences deduced from the α particles should match those from internal conversion.

Fig. 7 shows the α decay and internal conversion transition energies reported by Ellis (1932). Assuming that the highest-energy α decay of ^{212}Bi leads to the ground state of ^{208}Tl , the remaining α decays lead to the energy levels shown in the figure. The internal conversion lines then fit nicely into the same scheme of energy levels. For example, the energy difference of α_0 and α_1 is 41 keV,

Fig. 7 Differences in alpha decay energies (shown at right) agree with energy level intervals (shown in blue) from internal conversion electrons (Ellis, 1932) and with the presently accepted values of the energy levels shown at left. All energies are given in units of keV.

²In the early nuclear physics literature, all electrons were referred to as β particles, whether they came from β decay or internal conversion.

which agrees (within experimental uncertainty) with the 40 keV internal conversion transition energy. Similarly, the energy difference of α_0 and α_2 (332 keV) and that of α_1 and α_2 (291 keV) match the observed 327 and 287 keV internal conversion transitions. And so on through the remainder of the levels. The good agreement of the energy level differences reinforces the validity of the concept of discrete energy states in nuclei.

Yet another way to observe discrete energy levels of nuclei is through a nuclear reaction such as

in which a projectile x strikes a nucleus X , yielding a residual nucleus Y and an ejected particle y . The amount of energy available in the reaction is determined by the masses of the four particles. If the residual nucleus Y is formed in its lowest energy state, then the maximum amount of energy can be carried by the projectile y . If the residual nucleus Y is left in a higher energy state, then there is proportionately less energy given to the ejectile y . Thus by measuring the various energies of the emitted particles y , it is possible to determine the energy levels of Y (assuming no internal excitations of y can occur). This method for studying nuclear energy levels, which is common and routine today, was developed in the 1930s when accelerators for producing beams of projectiles x were newly available but limited in energy, and spectrometers for measuring the energies of y were less common. A summary of the state of research in this area is given by [Livingston and Bethe \(1937\)](#).

One of the earliest experiments of this type was reported by [Duncanson and Miller \(1934\)](#). They studied the reaction $\alpha + {}^{27}\text{Al} \rightarrow {}^{30}\text{Si} + \text{p}$, in which the α particles came not from an accelerator but from the radioactive decay of radium, and the outgoing protons were detected with a Geiger counter. They deduced energy levels in ${}^{30}\text{Si}$ of 2.23, 3.60, and 4.74 MeV and suggested the possible existence of γ rays of those energies. Similar attempts to deduce values of discrete energy levels were made in the earliest cyclotron experiments. For example, [McMillan and Lawrence \(1935\)](#) studied the reaction ${}^2\text{H} + {}^{27}\text{Al} \rightarrow {}^{28}\text{Al} + \text{p}$ using ${}^2\text{H}$ projectiles accelerated to 2.2 MeV and obtained values for several energy levels in ${}^{28}\text{Al}$.

Glossary

Beta decay The process by which one nucleus transforms into a nucleus with the same mass number but different atomic number.

Binding energy The difference in mass between a composite object and the sum total of its constituent objects, expressed in energy units.

Fission The breakup of a large nucleus into (generally) two smaller fragments.

Fusion The assembly of two lighter nuclei into one heavier nucleus.

Gamma emission The release of a photon in a transition between states in a nucleus.

Nucleon Collective name for a proton or neutron.

Introduction

A straightforward implication of quantum mechanics is that if matter is confined to a volume of a certain size, then the constituents of that matter must have internal momenta that are inversely proportional to the size scale. The electrons bound in an atom have energies on the order of several electron volts (eV). This is, therefore, roughly the size of the energy that can be released, per atom, in a chemical reaction. Examples would include the energy one gets by burning gasoline into carbon dioxide and water in an automobile engine, or released in a chemical explosion.

Each atom contains an atomic nucleus, at a distance scale roughly 100,000 times smaller than the size of the atom. The constituent particles of the nucleus are protons and neutrons, which we collectively refer to as nucleons. The much smaller distance scale implies much larger energies are released in nuclear reactions relative to chemical reactions, per “atom” of fuel.

This is the essential element of nuclear energy, the extremely high potential for energy release for a given amount of “fuel” as compared to conventional chemical reactions. Indeed immediately after the discovery of nuclear fission in 1939, its potential as an extremely powerful weapon was immediately recognized.

This chapter outlines the basic nuclear physics needed to understand the origin of nuclear energy. Numerical examples are given and essential feature are highlighted.

Equivalence of mass and energy

Energy is a profound concept in physics. One fundamental principle of Nature is that energy can neither be created nor destroyed. That is, energy is *conserved*. Another fundamental principle is that a system will always seek the state with the lowest possible energy. These two principles lead to the concept of *binding energy*, which provides a useful basis for discussing the release of energy in atomic and nuclear reactions.

If two particles attract each other, then we describe the attraction in terms of a *potential energy well*. (Indeed, the force itself is written as the negative of the gradient of the potential energy function.) Therefore, when two particles combine to form a more

complex object, the system finds itself in a lower potential energy state than for the two particles by themselves. If energy is to be conserved, however, then the energy difference between the initial and final states has to be somehow “released” in the combination reaction. This energy difference is called the *binding energy* of the system.

Of course, things can happen in the other direction. That is, a complex system made up of more elementary objects can be broken apart. In this case, an amount of energy equal to the binding energy needs to be introduced to the complex system.

This is a formal description of what happens when two particles interact with each other, but it begs the question regarding the physical origin of the binding energy. Students learn in most elementary classes that energy has different forms, for example, light and heat, and that these different forms can be converted from one to the other. But what is the form of energy that leads to binding of elementary particles?

The answer to this question lies in Einstein’s famous formula $E = mc^2$, which summarizes the equivalence between energy E and mass m , in terms of the speed of light c . A particle of mass m_1 binds to a particle of mass m_2 and forms an object with mass M where $M < m_1 + m_2$. The binding energy E_B is then $E_B = m_1c^2 + m_2c^2 - Mc^2$.

The binding energy for an electron and a singly ionized atom, also known as the *ionization potential*, is typically on the order of 10 electron volts (eV). The binding energy for nucleons in a nucleus is discussed below, but typically several millions of electron volts (MeV) for each proton or neutron in the nucleus. *This is the reason that nuclear energy is so much more powerful than the energy released in chemical reactions.* That is, the binding energy is roughly a million times larger in a nucleus than it is for electrons in atoms or molecules.

Protons and neutrons

Protons (p) and neutrons (n) are the particles that make up the nucleus. These two particles have very similar properties, and are often referred to collectively as *nucleons*. Their masses and interactions are fundamentally important to the binding energy of the nucleus and the source of nuclear energy.

One important similarity between protons and neutrons is that they have very nearly the same mass. Since we are discussing energies, we use the equivalence of mass and energy to express the masses of subatomic particles in energy units. For example, the mass of the proton is $938.27 \text{ MeV}/c^2$, and the mass of the neutron is $939.57 \text{ MeV}/c^2$. (The need for so many significant figures will become apparent shortly.) That is, the proton and neutron masses differ by only 0.13%. The electron mass, $0.51 \text{ MeV}/c^2$, is approximately 2000 times smaller than the mass of a nucleon.

Another important similarity between protons and neutrons is their intrinsic angular momentum, called *spin*. In both cases, the angular momentum has the nominal value $\hbar/2$, also referred to as *spin-1/2*. The origin of spin is purely quantum mechanical (Krane, 2021), and when particles are combined, the spins add as vector (i.e. signed) quantities. Thus, for example, two spin-1/2 particles can have a total spin of zero or one, and three spin-1/2 particles can have total spin 1/2 or 3/2.

An important difference between protons and neutrons is their electric charge. The proton has a positive charge $+e$, where e is the fundamental unit of charge. (That is, the charge of an electron is $-e$, so a neutral atom is made from a nucleus that has the same number of protons as the atom has electrons.) The neutron, on the other hand, has zero charge.

The hydrogen atom consists of an electron bound to a single proton. That is, the proton itself is the nucleus of the hydrogen atom. The binding energy of this atom is 13.6 eV, and is just due to the electrostatic attraction between the negatively charged electron and the positively charged proton.

The simplest complex nucleus, called the *deuteron*, consists of one proton bound to one neutron. (The atom composed of one electron bound to a deuteron is called *deuterium*.) The mass of the deuteron is $1875.61 \text{ MeV}/c^2$. The binding energy is then the difference between this and the sum of neutron and proton masses, that is

$$938.27 \text{ MeV}/c^2 + 939.57 \text{ MeV}/c^2 - 1875.61 \text{ MeV}/c^2 = 2.23 \text{ MeV}/c^2$$

This result is well known to nuclear physicists. If a low energy neutron encounters a free proton, it will be captured to form a deuteron and release a 2.2 MeV gamma ray.

The distributions of charge and matter in protons and neutrons are spread over some distance. The result is a nucleon that has “size,” described by a spherical distribution with a distance scale of roughly 0.5 fm. (One fm, called a “femtometer” or “fermi,” equals 10^{-15} m .) These distributions do not have a hard cutoff at any radial distance, however, so it would be misleading to refer to nucleons as “hard spheres.” Nevertheless, this distance scale is useful for understanding the properties of nuclei.

Descriptions and properties of the nucleus

Complex nuclei are essentially combinations of different numbers of protons and neutrons. The number of protons is denoted by Z , known as the “atomic number,” terminology borrowed from chemistry. Indeed, Z must also equal the number of electrons in the neutral atom. That is, the charge of a nucleus is simply $+Ze$. The number of neutrons is written as N , and the total number of neutrons plus protons is the “mass number” $A = Z + N$.

An *isotope* refers to a member of a nuclear species with the same atomic number but different mass number. That is, the same number of protons but a different number of neutrons.

Any nucleus is completely specified by the values of Z and A , with the value of N determined by arithmetic. Since Z also specifies the name of the element corresponding to the neutral atom, we use that name to identify the nucleus while using a left hand superscript to specify the mass number. So, for example,

$$^1\text{H}, ^2\text{H}, ^3\text{H}, ^3\text{He}, ^4\text{He}, ^{12}\text{C}, ^{14}\text{C}, ^{208}\text{Pb}, ^{235}\text{U}, ^{238}\text{U}$$

identify, respectively, the proton, deuteron, and triton (three isotopes of hydrogen), a rare isotope of helium, normal helium, the most abundant isotope of carbon, a radioactive isotope of carbon used to date human artifacts and other organic materials, the dominant isotope of lead, and two isotopes of uranium that are particularly relevant for nuclear energy.

The total angular momentum, or “spin,” of the nucleus depends on the particular orientation of the spins of the protons and neutrons as well as their motions within the nucleus. Nuclei have some number of *excited states* with energies higher than the ground state, and these excited states typically have different spins than the ground state.

Protons and neutrons have a finite size, and quantum mechanics forbids them to occupy the same space. Therefore, nuclei have a finite size that increases with mass number A . Quantifying the nuclear size depends on several details, including which distributions are being considered and the nuclear “shape” which may be other than spherical but a useful and simple formula is that the matter radius of a nucleus is given by

$$R = R_0 A^{1/3}$$

where $R_0 = 1.2$ fm. The factor $A^{1/3}$ is easy to understand, as the volume of a sphere packed with nucleons should be proportional to A .

Nuclear binding energy

The mass of a nucleus depends directly on its binding energy. When calculating the binding energy from the mass, it is important to recognize that tabulated atomic masses include the mass (and atomic binding energy) of the electrons that make up the neutral atom. In fact, atomic masses are generally reported in terms of the *atomic mass unit* $u = 931.494$ MeV/ c^2 , which is defined as exactly one-twelfth of the mass of the ^{12}C atom.

As an example, let us calculate the binding energy of the ^{12}C nucleus. To account for the mass of the electrons, it is convenient to use the mass of the hydrogen atom, 1.00784 u , instead of the proton. We have

$$\text{BE} = 6 \times (1.00784 \times 931.494) + 6 \times 939.57 - 12 \times 931.494 = 92.274 \text{ MeV}/c^2$$

(Note that this calculation ignores the binding energy of the electrons to the nucleus.) It is instructive to express this result as $\text{BE}/A = 7.69$ MeV per nucleon. That is, the binding energy of this nucleus is nearly as large as 1% of the nucleon mass.

This calculation can of course be carried out on any nucleus for which the mass is known. **Fig. 1** below plots the result, as binding energy per nucleon versus the mass number, for a large number of relatively abundant nuclei. (From https://commons.wikimedia.org/wiki/File:Binding_energy_curve_-_common_isotopes.svg.)

Fig. 1 Plot of the average binding energy per nucleon as a function of atomic mass A , averaged over the stable nuclei with that mass number. This generally smooth shape is well predicted by the Weizsäcker mass formula. The most stable nuclei are in the mass numbers near iron ($Z = 26$). There is a significant departure from the smooth curve for the ^4He nucleus, which is especially tightly bound.

Fig. 2 The binding energy per nucleon for isotopes of copper ($Z = 29$), demonstrating the difference in pairing energy for odd or even numbers of neutrons.

A number of conclusions can be immediately drawn from this figure. Firstly, for the large majority of nuclei, the binding energy per nucleon is nearly constant, roughly equal to 8.5 MeV for nuclei heavier than oxygen. Secondly, the nuclei fall more or less on a smooth curve, rising rapidly for the light nuclei, reaching a maximum near ^{56}Fe , and then steadily decreasing through to uranium. This smooth shape is interrupted by a few particularly tightly bound nuclei, namely ^4He , ^{12}C , and ^{16}O .

These observations are key to understanding the fundamental sources of nuclear energy. Energy will be released if a large nucleus such as uranium breaks into smaller pieces that are larger than iron. This process is known as “nuclear fission.” Similarly, energy will be released if the light nuclei with $A = 1, 2$, and 3 combine to form ^4He , a process known as “nuclear fusion.” These processes are discussed below in more detail.

The smooth curve of the binding energy per nucleon versus mass number, is well described by the semi-empirical Weizsäcker mass formula. This formula expresses the binding energy E_B as a function of A , and is given by

$$E_B = a_V A - a_S A^{2/3} - a_C Z(Z-1)/A^{1/3} - a_A (A - 2Z)^2/A \pm \delta(Z, A)$$

These terms take into account, respectively, the overall binding of the A nucleons, a repulsive effect from “surface tension” of the nucleus, the electrostatic Coulomb repulsion of the protons, an “asymmetry” contribution from the “dilution” of coulomb repulsion by neutrons in heavy nuclei, and a quantum mechanical “pairing” energy that prefers neutrons and protons to come in pairs. The specific values of the coefficients a_i depend on the data set to which this formula is fit, but are given by (in MeV) to within a few percent as $a_V = 15.5$, $a_S = 16.8$, $a_C = 0.72$, and $a_A = 23$. The pair energy is reasonably approximated as $\delta(Z, A) = +a_P A^{-3/4}$ if Z and N are both even, $-a_P A^{-3/4}$ if Z and N are both odd, where $a_P = 34$ MeV, and zero if A is odd.

The “asymmetry” and “pairing” energies are nicely demonstrated in Fig. 2, which plots the binding energy per nucleon for isotopes of copper ($Z = 29$). The even isotopes (blue circles) and the odd isotopes (orange squares) are clearly separated from each other because of the pairing energy, but the overall trend for each is a parabolic dependence on the mass number, as expected from the Weizsäcker mass formula.

Nuclear interactions

The source of the binding energy of nucleons in a nucleus, called the *Strong Force*, acts only over very short distances, on the order of one femtometer (fm). It is therefore unfamiliar at the atomic scale, but nevertheless is responsible for overcoming the Coulomb repulsion of protons in the nucleus.

The exceptionally short range of the strong force is understood in the context of quantum field theory. In this framework, two particles interact with each other by virtue of an “exchange” particle. If the exchange particle is massive, then it is straightforward to show that the range of the interaction is inversely proportional to the mass. A range of 1 fm corresponds to an exchange particle mass of roughly $200 \text{ MeV}/c^2$, and this led to the discovery of the π -meson, or “pion,” with mass $135 \text{ MeV}/c^2$, as the exchange particle of the strong interaction.

Other components of the strong force are repulsive. These correspond to exchange particles other than the pion, which in fact are more massive and therefore of shorter range. The result is that nucleons are “packed” into a nuclear volume that is proportional to $A^{1/3}$. This is also responsible for the binding energy being proportional to the volume of the nucleus, to first approximation, as indicated in the Weizsäcker mass formula. The Coulomb force, however, is long range, so additional neutrons are needed to “dilute” the electrostatic repulsion and hold the nucleus together, as the atomic number increases.

During the process of nuclear fission, a large nucleus splits apart into two fragments. (This is discussed in more detail below.) The fragments are separated from each other by nuclear scale distances, but this is far enough so that the strong force becomes very weak, and Coulomb repulsion takes over. It is in this way that energy is released in nuclear fission.

A second interaction which only manifests itself at nuclear (and subnuclear) distances is the *Weak Interaction*. Mediated by exchange particles nearly one thousand times as massive as the pion, this interaction contributes only a minute amount to the

nuclear binding energy. However, in this case, the exchange particles allow the transformation of neutrons into protons, or vice versa, with the creation of other particles, including electrons, positrons (antimatter forms of electrons), and neutrinos.

Extracting nuclear energy: Fission, fusion, and radioactive decay

Now we have enough information to understand the dominant forms of energy release in nuclear reactions. These are “fission,” when a heavy nucleus splits into two fragments; “fusion,” when very light nuclei combine to make a heavier nucleus; and “beta decay,” when the weak interaction releases energy in the form of much lighter particles during transformations between neutrons and protons and “gamma decay” when a nucleus makes a transition from an excited state to a lower energy state. Indeed, radioactive decay itself provides a mechanism for extracting nuclear energy for practical applications.

Fission

Isotopes of iron ($Z = 26$) are particularly stable nuclei, with especially high binding energy per nucleon. Therefore, any nucleus with $Z > 52$ or so is less stable than the sum of the two nuclear fragments into which it would break up. In most cases, this does not happen spontaneously because the surface tension energy required to deform the large nucleus presents a barrier. However, in a number of special cases, the breakup of a large nucleus into two fragments, called “nuclear fission,” can be generated in controlled ways so that the resulting released energy is usefully harnessed.

Probably the most familiar example is the isotope ^{235}U , which provides the energy behind commercial nuclear power generators and many forms of nuclear weapons. A very low energy neutron is readily absorbed the ^{235}U which subsequently breaks into two large fragments. (In fact, typically a few neutrons are also released during fission process, and these can be used to propagate a chain reaction.)

A key aspect of ^{235}U is that it has an odd number of neutrons. The addition of even a very low energy neutron causes the nucleus to undergo fission, because of the binding attributed to the pairing energy. The nucleus ^{238}U also undergoes fission in the presence of neutrons, but only if the neutrons have high enough energy to overcome the fission barrier presented by the surface tension. In particular, ^{235}U will undergo fission by “thermal” neutrons, that is, neutrons in equilibrium with the thermal environment, namely with energies much less than 1 eV. Neutron induced fission of ^{238}U , on the other hand, requires neutrons with energies of more than 1 MeV.

Most natural uranium consists of the isotope ^{238}U . The natural isotopic abundance of ^{235}U is very small, less than 1%. Therefore, in many applications where fission is to be generated by thermal neutrons, for example nuclear reactors, natural uranium is “enriched” in ^{235}U to some level.

Let us investigate the energetics of ^{236}U (that is $^{235}\text{U} + n$) breakup and use this as an example of energy release in nuclear fission. Fission is notoriously asymmetric, so for the sake of illustration we assume ^{236}U splits into ^{133}Sn ($Z = 50$) and ^{103}Mo ($Z = 42$). The Weizsäcker mass formula tells us that the binding energies per nucleon for these three isotopes are 7.532 MeV, 8.224 MeV, and 8.542 MeV. (Compare these numbers to those plotted in the figure of binding energy per nucleon as a function of A .) The total energy released is

$$133 \times 8.224 + 103 \times 8.565 - 236 \times 7.538 = 196.5 \text{ MeV}$$

We have suggested that this energy appears in the Coulomb repulsion of the two fragments, so let’s test this idea. Using $R = R_0 A^{1/3}$ the radii of the two fragments ^{132}Sn and ^{103}Mo are 6.1 and 5.6 fm, respectively. Take these fragments to be two charged spheres that are just touching, so the centers are separated by $d = 11.7$ fm. The Coulomb energy just after fission is

$$(1/4\pi\epsilon_0) Z_1 Z_2 e^2/d = 258 \text{ MeV}$$

This is a crude calculation, involving several rough approximations, but the two calculations give results that are surprisingly close. In other words, the result of a fission of a heavy nucleus is that the fragments fly away from each other by virtue of their electrostatic repulsion. In other words, nearly all the energy released in fission appears in the kinetic energy of the fragments. The fragments slow down in the surrounding matter, imparting heat. This is the essence of how a nuclear power reactor generates steam to run turbines, for example.

Fusion

Quantum mechanical effects in very light nuclei lead to peculiar results for nuclear binding energy, as shown in the figure of binding energy per nucleon. In particular, combinations of isotopes of hydrogen (^1H , ^2H , and ^3H) and ^3He into ^4He leads to a very large increase in the binding energy per nucleon, because ^4He is exceptionally tightly bound. Such processes are referred to as “nuclear fusion” and are in principle very copious sources of nuclear energy.

It is not obvious how to identify practical fusion reactions for generating nuclear power. Of the four lightest isotopes, the most abundant by far is simple hydrogen, that is ^1H . However, converting four ^1H into one ^4He requires turning two protons into neutrons. This can only happen through the weak interaction, so reaction rates will be very small. Indeed, this is how the Sun and other stars produce energy, but this is only possible because the temperatures and pressures in their cores are extraordinarily

large. Direct fusion of two ^2H into one ^4He is possible, through the reaction $^2\text{H} + ^2\text{H} \rightarrow ^4\text{He} + \gamma$. However in this case another interaction, the electromagnetic interaction, is required, which again is much weaker than the strong interaction.

Practical fusion reactions instead make use of “*dt* fusion,” that is, the fusion of a deuteron with a triton, in the reaction.

Although deuterium (^2H) is very rare (approximately 0.01% of the hydrogen on Earth), and tritium (^3H) is radioactive (with a half-life of only 12.3 years and therefore exists on Earth at impractical to use low concentrations), the energetics of this reaction are so favorable that the results are well worth the hurdles that need to be overcome.

The energy release in *dt* fusion is $M(^2\text{H}) + M(^3\text{H}) - M(^4\text{He}) - M(\text{n})$. Using the atomic (and neutron) masses, this is

$$(2.01410 + 3.01605 - 4.00260) \times 931.4941 - 939.565 = 17.6 \text{ MeV}$$

In other words, the energy release per unit of atomic mass is more than 3 MeV for fusion, whereas for fission it is closer to 1 MeV. That is, fusion is much more efficient energy source. Furthermore, it has the added benefit that the reaction products are considerably more benign than the radioactive daughter isotopes produced in fission.

The energy released in *dt* fusion is shared by the helium nucleus and neutron, with 4/5 of the energy (14 MeV) being carried off by the neutron. Harnessing this kinetic energy is one of the objectives of fusion reactor designers (Morse, 2021; Boccaccini, 2021). Another objective is converting the neutron to a triton via capture in ^6Li and (*n*,2*n*) reaction with ^7Li .

Radioactive decay

The radioactive decay of unstable nuclei is by itself a significant source of nuclear energy. Details of radioactivity are covered in Previtali (2021). One point made in particular, is that the heat of the Earth’s core is driven by the decay of radioactive isotopes. This has in fact been confirmed experimentally by detecting the neutrinos from the relevant beta decay processes.

^{238}U is one of the isotopes responsible for the heating at the core of the Earth. The radioactive decay chain of ^{238}U proceeds through eight alpha decays and six beta decays, ending up at ^{206}Pb . (Shusterman, 2021). From the mass difference of ^{238}U and ^{206}Pb and including the mass of the alpha particles, we find 48 MeV of energy released for each decaying ^{238}U nucleus. (In this calculation, we take only half the energy released in the beta decays, assuming that the other half is carried away by the neutrinos.)

Beta decay of the radioactive daughter nuclei in fission is also a significant source of energy in nuclear reactors. Heavier nuclei require relatively more neutrons for stability against Coulomb repulsion than do lighter nuclei, so the daughter nuclei are “neutron rich.” Therefore, they beta decay by turning neutrons into protons, releasing electrons in the process. Each daughter nucleus leads, typically, to three beta decays before turning into a stable nucleus, with each electron from the decay carrying roughly 1 MeV of energy. Thus the beta electron energy is roughly 6 MeV per fission, or about 2% of the energy released in the fission process itself. Beta decays also often produce nuclei in excited states that subsequently decay by emitting gamma rays.

Radioactive Thermal Generators (RTGs) make a practical use of nuclear energy released in radioactive decay, and one that is particularly useful when long term reliability is required in situations where maintenance is difficult or impossible, or where sunshine for solar power is lacking. In fact RTGs find many uses in space exploration (Previtali, 2021; Bennett, 2021). To be useful, an isotope must have a long enough half-life so that it spans the anticipated useful life of the application, but short enough so that the decay rate provides a reasonable power output per gram of material. The decay products are preferably dominated by alpha and beta emission, as neutrons and gamma rays are more difficult to stop, so would require more material surrounding the source to collect the energy.

The isotope ^{238}Pu is a generally attractive option for RTGs. It has a half-life of 87.7 years, and decays virtually 100% by alpha emission. Nearly 71% of the decays go to the ground state of ^{234}U , releasing a 5.5 MeV alpha particle, with nearly all remaining decays to the 43.4 keV excited state, which itself decays by gamma emission. We can confirm the energetics of ^{238}Pu decay by considering the difference of mass between this nucleus (238.0496u) and the daughter ^{234}U (234.0410u) plus an alpha particle. The result is 5.6 MeV, where 0.1 MeV is carried off by ^{234}U .

Radioactive decays

Radioactivity is generated by spontaneous transitions of nuclei from their original states to other states to reach a more stable nuclear configuration. During this process, the excess energy is released by the emission of particles. Based on the emitted particle, we can classify the type of decay that drives the nucleus from the initial to the final state. From this point we can identify three main radioactive decay modes:

- Alpha decay
- Beta decay
- Gamma decay

Alpha decay

Alpha decay is directly related with the electromagnetic forces produced inside the nucleus by protons that create the condition for the emission of a ${}^4\text{He}$ nucleus: the so-called alpha particle. To represent such nuclear decay, we can write:

$$(AZ) \rightarrow (A - 4, Z - 2) + \alpha$$

In this transition the parent nucleus (A, Z) will release the α particle leaving the daughter nucleus with $N-2$ neutrons and $Z-2$ protons. This process will release energy equal to:

$$Q = [m(A, Z) - m(A - 4, Z - 2) - m_\alpha] c^2$$

where $m(A, Z)$ is the mass of the parent nucleus; $m(A-4, Z-2)$ is the mass of the daughter nucleus. m_α is the mass of the alpha particle, in other words the mass of the ${}^4\text{He}$ nucleus.

Applying this calculation to possible parents and daughter nucleus it is evident that alpha decays are possible only if $Q > 0$. Considering the average binding energy per nucleon, this relation clearly explains why alpha decays nuclei are concentrated in the high mass region. In practice only if the parent nucleus exhibits a binding energy per nucleon similar to that of the ${}^4\text{He}$ nucleus, could it be possible to have an alpha decay.

The Q value represents the total energy that will be released in the decay. For the alpha decay process in which there are two nuclei in the final state, the Q value will be distributed between the kinetic energies of the two products:

$$Q = T_\alpha + T_{(A-4, Z-2)}$$

Considering the parent nucleus to be at rest and using momentum and energy conservation, it is possible to evaluate the kinetic energy acquired by the alpha particle in the decay:

$$T = Q / \left[1 + \left(m_\alpha / m_{(A-4, Z-2)} \right) \right]$$

Considering the mass of the daughter nucleus, the alpha particle will acquire almost 98% of the Q value of the decay.

It is possible to evaluate the alpha decay probability starting from a simple model in which the alpha particle is trapped inside the Coulomb barrier generated by the daughter nucleus. The alpha particle can escape from the nucleus only because of the

quantum mechanical tunnelling effect. Using the Schrodinger equation for the penetration of a barrier, it is possible to evaluate the half life of an alpha decaying nucleus:

$$\frac{1}{T_{1/2}} \approx \frac{h}{m_\alpha R_n^2} \exp \left[-\frac{2}{h} \int_{R_n}^{R_n+d} \sqrt{2 m_\alpha (U(r) - E)} dr \right]$$

Where R_n is the radius of the nucleus, $U(r)$ is the barrier potential and E is the energy of the decay. It is important to observe that there is an exponential relationship between the half life and the energy of the alpha decay (Krane, 1987). This implies that a small variation in the Q value translates into a large change in the half life. In natural radioactive alpha decays, the Q values ranges from 2 MeV to 9 MeV but half life values range from fractions of microsecond to more than 10^{10} years.

Fig. 1 represents the alpha decay scheme of the ^{238}U nucleus. It is interesting to see how the transition probability indicated by the previous formula, strongly suppress the alpha decays to excited states of the daughter nucleus due to the reduction of the alpha decay energy E .

Beta decay

In the beta decay transition, there is no change in the atomic mass number of the nucleus. Depending on whether a neutron is transformed into a proton or vice versa, three different processes can take place:

$$\beta^- \quad (AZ) \rightarrow (AZ + 1) + e^- + \nu_e$$

$$\beta^+ \quad (AZ) \rightarrow (AZ - 1) + e^+ + \nu_e$$

$$EC \quad (AZ) + e^- \rightarrow (AZ - 1) + \nu_e$$

where the various symbols indicate: e^- the electron and e^+ the positron, $\nu_e(\bar{\nu}_e)$ the (anti)neutrino, and EC indicates atomic electron capture decay.

The neutrino was postulated as a new particle at the beginning of the 1930s by W. Pauli to justify the apparent non-conservation of energy produced by the emitted electron in beta decay (CERN, 2013). The name "neutrino" was introduced by Fermi (1934a,b) to distinguish such neutral particles from the other one discovered in the same period that was called the neutron. Neutrino interactions with matter have extremely low probability and the first observation of such interaction was made by Cowan Jr. et al. (1956).

Looking at the three indicated decay channels, the first one (β^-) transforms the parent to the daughter nucleus increasing the atomic number by one unit. On the contrary, the other two channels (β^+ , EC) both decrease the atomic number by one unit. To understand why we need two channels in which a proton can be transformed into a neutron inside the nucleus, we have to examine the energy conditions necessary for each of the three decay modes:

$$\beta^- \quad m(A, Z) > m(A, Z + 1) + m_e$$

where m is the nuclear mass and m_e is the mass of the electron (under the reasonable hypothesis that $m_\nu = 0$). Adding $(Z * m_e)$ on both sides of the equation, we obtain the equivalent condition using atomic masses (M):

Fig. 1 Alpha decay scheme of the ^{238}U nucleus. The production of excited states in the daughter nucleus is strongly disfavored.

$$\beta^- \quad M(A, Z) > M(A, Z+1)$$

The result indicates that if the mass of the parent atom is larger than the mass of the daughter then β^- decay is energetically possible.

We can proceed in the same way for the other two decay channels.

$$\beta^+ \quad m(A, Z) > m(A, Z-1) + m_e$$

Adding $(Z * m_e)$ on both sides of the equation:

$$\beta^+ \quad M(A, Z) > M(A, Z-1) + 2*m_e$$

In the case of β^+ , the decay is energetically possible only if the mass of the parent atom is larger than the daughter one plus 2 electron masses. With this condition the β^+ decay will take place only if the energy mass difference between the two involved atoms is above a threshold of $2 * m_e = 1.022 \text{ MeV}$.

Now we can apply the same procedure to the process in which the nucleus captures an electron from the atomic shells:

$$EC \quad m(A, Z) + m_e > m(A, Z-1)$$

In this case we add $(Z-1) * m_e$ on the two sides of the equation:

$$EC \quad M(A, Z) > M(A, Z-1)$$

No threshold is present in this case. In the EC decay process, an atomic electron is captured by the nucleus. The EC decay probability depends on the overlap of the wave functions of the nucleus and the electron. Increasing the Z of the atom causes this overlap to increase which produces larger EC transition probabilities for heavy nuclei. This implies that mainly the electrons close to the nucleus will be captured. As a result, the binding energy of the atomic shell has to be considered in the total decay energy balance.

In β^- and β^+ decays there are three particles in the final state: the daughter nucleus, the electron (positron) and the (anti) neutrino. The energy released by the decay is shared mainly by the two emitted particles. Nuclear recoil can be considered as less important, but all the particles participate in sharing of the linear momentum. The energy spectrum of the electron is continuous starting from zero up to the Q value of the beta transition and (neglecting the nuclear recoil energy) obviously we have that:

$$Q = T_e + T_\nu$$

The shape of the energy spectrum is strongly related to the decay transition type, and depending on the characteristics of the initial and the final states we can produce a detailed classification of the beta decays (Konopinski, 1943).

Considering only the allowed beta decay transitions, we can write the electron energy spectrum in a relatively simple way as:

$$\frac{dN}{dE} = N_0 \frac{16\pi^2}{c^4} D \sqrt{E(E + 2m_e c^2)} (E - m_e c^2) (E_m - E)^2 F(Z, E)$$

where D is a proportionality factor, E is the electron energy expressed in electron mass units, E_m is the maximum energy acquired by the electron, and $F(Z, E)$ is the so-called Fermi factor that takes into account the electromagnetic correction to the decay spectrum.

The main difference between the β^- and β^+ spectra can be observed in the low energy part of the electron (positron) energy spectrum where the different electric charges of the electron and the positron play an important role.

We can now evaluate the half-life starting from the energy distribution of the electrons and integrating the previous formula:

$$\frac{1}{T_{1/2}} = \frac{1}{\ln 2} \frac{16\pi^2}{c^4} D \int_0^{E_m} \sqrt{E(E + 2m_e c^2)} (E - m_e c^2) (E_m - E)^2 F(Z, E) dE$$

Without entering into the details of the integral solution that requires a precise description of the Fermi factor, we consider only the case in which $E_m \gg m_e c^2$ obtaining an energy dependence for the half life:

$$\frac{1}{T_{1/2}} \propto E_m^5$$

We immediately observe that the decay probability for beta decays depends less strongly on the transition energy as compared with alpha decay described in the previous paragraph. With this dependence, possible transitions to excited states of the daughter nucleus are less suppressed than those for alpha decay. Considering the emitted particles in the final state, it is clear that the electron and neutrino spins contribute to a maximum change in the nuclear angular momenta of one unit. Such decays are identified as allowed transitions. All the other changes in nuclear angular momenta imply different angular momentum for the electron or neutrino in the final states and are normally labeled as forbidden transitions (Konopinski, 1943).

In Fig. 2, the beta transition scheme of ^{60}Co is illustrated. Due to the large variation of the angular momentum between the ground state of the parent nucleus and the ground state of the daughter one, beta transition to excited states are strongly favored with subsequent emission of gamma ray photons.

We now have to raise an important question: for β^- and β^+ decays we can observe the emitted charged particles as indicated in the transition schemes. What is the observable for the EC decay channel? It is important to remember that in this transition an

Fig. 2 Beta decay scheme of the ^{60}Co nucleus. The large difference in angular momentum between the ground state of the parent nucleus and that of the ground state of the daughter strongly favors the population of excited states and subsequent emission of gamma ray photons.

atomic electron is captured by the nucleus. As a result, there will be a hole in one of the shells of the daughter atom that will be filled by means of electron rearrangements. As a consequence, characteristic X-rays will be emitted from the daughter atom.

Gamma decay

A nucleus in an excited state will undergo gamma decay to reach a more stable nuclear configuration. Normally a photon with an energy equal to the energy difference between the initial and final state is emitted: this photon is usually identified as gamma ray.

$$(A, Z)^* \rightarrow (A, Z) + \gamma$$

The * indicates a nucleus in an excited state. In this case the energy balance is relatively simple (again neglecting nuclear recoil):

$$E_\gamma = E_n^i - E_n^f$$

where i and f indicate the initial and final states of the nucleus.

In what way can a nucleus reach an excited state? Normally it is the result of a previous alpha or beta decay or it is due to a nuclear reaction. Due to the decay probability, alpha decay normally generates the daughter nucleus in the ground state and if an excited state is produced it is usually of relatively low energy. In the case of beta decay, the conservation rules for angular momentum frequently generates a daughter nucleus in excited states that normally produces gamma transitions to reach the final ground state.

The typical energies of gamma ray photons are on the order of an MeV. For lower energy transitions another important process occurs: the conversion electron transition. In such case the energy of the excited nucleus is transferred directly to an atomic electron that will be emitted with an energy equal to the difference between the nuclear excited state and the atomic electron binding energy.

$$E_e = E_n^i - E_n^f - B(Z)_e$$

where B indicates the atomic electron binding energy. The conversion electron process is strictly connected with the overlap of the nuclear and atomic wave functions.

The timescale for gamma decays is normally very short. This is an electromagnetic transition, and the process will take place on times typically of the order of few psec (10^{-12} s). This is the reason why normally we associate the emitted gamma decay with the name of the beta or alpha parent nucleus, even though the gamma emission is produced by the daughter.

There are some cases in which the daughter nucleus remains in an excited state for a long time. In such cases the states are called metastable, and the nuclei that have such states are indicated as metastable nuclei. In many cases these nuclei will remain in excited states for times longer than months or years. In such cases it is obviously not possible to directly correlate the emitted gamma ray with the previous nuclear transition.

Source of Earth's internal heating

Our Solar System was born approximately 5 billion years ago from material expelled by previous generations of stars that produced all the elements that we now find on Earth. Among these elements, we find many radioactive isotopes still present in the Earth. These isotopes generate the so-called fossil radioactivity that is the most important part of the natural radioactivity on Earth. In order

to be considered as a fossil radioactivity element, the half lifetimes of such unstable nuclei have to be on the order of the age of the Solar System. We can also classify such radioactive elements in two main groups: radioactive isotopes that undergo a transition to stable nuclei or that are parents of a relatively long radioactive chain.

Radioactive chains

The radioactive chains are mainly produced by heavy nuclei. We normally identify four chains due to the dominant alpha decays that change the nuclear masses by four units. More specifically the four chains are:

$$\begin{aligned} A = 4n \quad {}^{232}_{90}\text{Th} \quad T_{1/2} &= 1.4 \cdot 10^{10} \text{ years} \\ A = 4n + 1 \quad {}^{237}_{93}\text{Np} \quad T_{1/2} &= 2.2 \cdot 10^6 \text{ years} \\ A = 4n + 2 \quad {}^{238}_{92}\text{U} \quad T_{1/2} &= 4.6 \cdot 10^9 \text{ years} \\ A = 4n + 3 \quad {}^{235}_{92}\text{U} \quad T_{1/2} &= 7.8 \cdot 10^8 \text{ years} \end{aligned}$$

Looking at the half lives of the four parent nuclei, it is clear that after 5 Gy, ${}^{237}\text{Np}$ has completely disappeared; ${}^{235}\text{U}$ is strongly reduced with respect to its original abundance; ${}^{238}\text{U}$ is now one half its initial value, and ${}^{232}\text{Th}$ is almost unchanged (Nucleardata, 1999). So at present, there are two main chains that are important for natural radioactivity.

In general, the parent nuclei will undergo a transition to a daughter that is also radioactive, and the daughter of the daughter (granddaughter) is also radioactive. In this way we can identify around 10 nuclei that directly derive from the progenitors: this generates the radioactive chains. The full chains of ${}^{232}\text{Th}$, ${}^{238}\text{U}$ and ${}^{235}\text{U}$ are represented in Figs. 3–5 respectively. Normally the last element of the chain is a stable lead isotope (Nucleardata, 1999).

The radioactive chains are dominated by the alpha decay with some beta minus transitions that are necessary in order to counterbalance the increase of the neutron/proton ratio generated by the alpha decays. The chain will reach secular equilibrium (all the nuclei involved in the chain show the same activity) after about five half lives of the daughter nucleus with the longest half life. This means that in order to reach secular equilibrium, the radioactive chains must remain isolated for a time related with the half lives of the daughter nuclei. If we consider the ${}^{232}\text{Th}$ chain, we see that the daughter nucleus with the longest half life is ${}^{228}\text{Ra}$, with $T_{1/2} \sim 5$ years (Nucleardata, 1999). Secular equilibrium will be reached in the relatively short time of around 25 years. On the contrary, the longest half life daughter of the ${}^{238}\text{U}$ chain is ${}^{234}\text{U}$ with $T_{1/2} \sim 2.5 \cdot 10^5$ years (Nucleardata, 1999). This means that at least a million years is needed to put the chain in the secular equilibrium condition.

Within the radioactive chains there are some elements that easily break the chains. Typically, Radium is an alkaline metal and under the action of a polar solvent (e.g. water) it can be released from rock and in such a way will break the chain into two parts. The same situation happens for Radon, which is a noble gas and does not establish chemical bounds with the materials in which it is produced. Consequently, Radon can be released by rocks and diffuse into the atmosphere or water generating a break in the radioactive chains. In all these cases, the mechanisms for radioactive chains breaks are strongly connected with the characteristics of the rocks and also with the half lives of the radioactive isotopes of Radium and Radon.

Long living radioactive isotopes

Apart from the radioactive chains described in the previous paragraph, there are also some other fossil radioactive isotopes present on Earth. These isotopes have a half life of the same order of the age of the Earth.

The most important isotope of this type is ${}^{40}\text{K}$ that has a half life of $T_{1/2} \sim 1.3 \cdot 10^9$ years. Its isotopic abundance is relatively low, 0.0118% (Nucleardata, 1999), but the concentration of Potassium on Earth is relatively high and that implies that the contribution to the natural radioactivity from this isotope is very important. Just to have an idea, inside each of our bodies there are approximately 4000 decays per second of ${}^{40}\text{K}$. This isotope decays by beta minus, $BR \sim 90\%$, and by electron capture $BR \sim 10\%$.

Another fossil isotope is ${}^{87}\text{Rb}$ that has a half life of $T_{1/2} \sim 4.8 \cdot 10^{10}$ years and an isotopic abundance of 27.8% (Nucleardata, 1999). ${}^{87}\text{Rb}$ also decays via a beta transition but, considering that the concentration of Rubidium on Earth is not so large, the overall contribution of this isotope to the Earth's radioactivity is relatively low.

An interesting case relates to ${}^{209}\text{Bi}$: $T_{1/2} \sim 2 \cdot 10^{19}$ years and isotopic abundance 100% (Nucleardata, 1999). This is the last remaining radioactive isotope of the ${}^{237}\text{Np}$ chain that, due to its relatively short half life has practically disappeared on Earth. The very long half lifetime of ${}^{209}\text{Bi}$ implies that its global contribution to the Earth radioactivity is extremely low and it could be considered, under many points of view, as a stable nucleus.

The radioactivity heat of the Earth

Looking to the natural radioactivity, it is reasonable to imagine that the energy released by the radioactive decays could contribute to the geothermal heat of the Earth. The question is how important is the contribution that comes from radioactivity with respect to what we observe from the thermal point of view.

In order to answer this question, there have been measurements that attempt to quantify the total number of radioactive decays per second that occur in the Earth's crust and mantle. Considering the main radioactive isotopes that could contribute to this energy

Fig. 3 ^{232}Th radioactive chain with the most important emitted alpha, beta and gamma radiations. Reported data from <http://nucleardata.nuclear.lu.se/toi/>

Fig. 4 ^{238}U radioactive chain with the most important emitted alpha, beta and gamma radiations. Reported data from <http://nucleardata.nuclear.lu.se/toi/>

Fig. 5 ^{235}U radioactive chain with the most important emitted alpha, beta and gamma radiations. Reported data from <http://nucleardata.nuclear.lu.se/toi/>

release, we can identify ^{232}Th , ^{238}U and ^{40}K . All these isotopes are part of the Earth's ores and release their decay energy within the Earth's volume. To quantify the Earth's radioactivity, dedicated measurements of anti-neutrino fluxes from the Earth (geo-neutrinos) were done. Anti-neutrinos are produced by beta decays of the previously mentioned radioactive sources and their observation provides a direct quantification of the global radioactivity of the Earth. Geo-antineutrinos travel over a long distance inside the Earth's mantle and crust thanks to their very small interaction cross sections. To detect them, experiments typically use the inverse beta decay reaction:

Only geo-antineutrinos with an energy above 1.8 MeV can induce this reaction, so these experiments can only detect decays from the ^{238}U and ^{232}Th chains and not ^{40}K . These measurements are sensitive to mantle radioactivity that is not accessible with direct sampling or with other radioactivity measurements. Important results were obtained by Borexino and Kamland experiments that clearly identified the anti-neutrino signal that comes from the internal part of the Earth and determine the radiogenic heat from ^{238}U and ^{232}Th chains in the mantle of the order of 24 TW of power (Agostini et al., 2020; Gando et al., 2011).

In parallel with the anti-neutrino measurements, evaluations of the radioactivity of rocks and sediments in the Earth's crust were performed in order to identify the mean concentration of radioactive sources. These measurements determine the radioactivity from all the radioactive chains and for ^{40}K . Combining these results with those from the geo-antineutrino experiments, the total radiogenic heat for the Earth was determined to be equal to 38 TW of power, with an error of the order of 30% (Agostini et al., 2020). The results obtained with these measurements are compatible with a relatively high concentration of radioactive elements inside the Earth. If we compare these experimental results with the estimated total heat of the Earth to be around 47 TW (Davies and Davies, 2010) of power, we conclude that radioactive decay is the main source of geothermal heat.

Radioactive energy source for remote applications

Radioactive decay is an exothermic process and decay transitions release energy to the final decay products. The result is a net flux of energy that can generate thermal power. Selecting a suitable decay source, a radioactive energy generator can be used in many different applications.

The big advantage of this approach is connected to the large amount of energy produced by radioactive decays as compared to chemical reactions. By selecting long-lived isotopes, energy can be produced for long periods of time. Another important feature is that radioactive decay is not affected by environmental conditions. High vacuum conditions in space, high temperatures or high pressures don't affect the radioactive decay. Moreover, the radioactive source will remain in operation without any maintenance.

On the other hand, radioactive generators have low power density and low electrical conversion efficiency. Also, the application of such power generators is normally considered only for applications in which there are difficulties to actively manage the power sources. Examples include space stations and remote environmental instruments, or in situations in which possible recharging/refueling of the power source is difficult, or for implanted pacemakers for heartbeat stabilization.

The first aspect that has to be considered is the total radioactive power needed to guaranty a reasonable energy production. Just as an example, to generate 1 mW of power starting from a radioactive source that releases 1 MeV of energy per decay, a total activity of around 10^{10} Bq (0.3 Ci) is needed and, taking also into account a reasonable energy conversion efficiency, an increase of around a factor 10 in the total source activity is needed. This implies that few grams of ^{226}Ra , for example, are necessary (Nucleardata, 1999). This relatively large amount of radioactive material has to be taken into account because of potential safety issues for users and because it also has an impact on the costs of radioactive energy generators.

Alpha decay transitions will guaranty a large energy release per decay and safe operation of radioactive batteries (Knoll, 2010). On the contrary, beta decays are often connected with gamma emissions and, even in case of pure beta transitions, photons from bremsstrahlung of electrons can be emitted by the radioactive sources (Knoll, 2010). To increase the power density generated by the radioactive sources, nuclei with not too long half lives have to be selected. The most widely radioactive source used for these applications is ^{238}Pu . It has an alpha decay with a total energy of 5.5 MeV, a half life of 87 years and low probability for gamma ray and neutron emissions (Nucleardata, 1999). The main issue of such source is related with its relatively high production costs. However, with nuclear waste reprocessing it will be possible to generate strong radioactive ^{90}Sr sources at relatively low cost. This transition is a pure beta decay with practically no gamma ray emissions (Nucleardata, 1999), but it needs substantial radiation shields to stop the high energy electrons and their generated bremsstrahlung photons.

Radioisotope thermal generators (RTG)

In the most straightforward approach, to convert the radioactive decay energy into electric power the emitted particles interact with the source materials. These interactions produce a net increase of the material temperature that can be converted in electricity via various thermodynamic approaches: thermocouples, Peltier cells, or Stirling Engines.

Depending on the selected conversion technique, thermodynamic efficiency can vary substantially. A standard RTG made with thermocouples or Peltier cells has an energy conversion efficiency below 10%. However, applying the radioactive source to a Stirling motor generator a thermodynamic efficiency well above 20% was demonstrated

One of the main uses of RTGs is connected with space applications (NTRS, 2018). NASA has implemented RTGs since the Apollo missions in the 1960s. Long lasting space missions are directly supported by the long living radioactive isotopes for onsite electrical power production. The installation of an RTG on the Curiosity Rover on Mars will guaranty a long running time operation of the installed instrumentation.

Direct and indirect conversion batteries

A different strategy is related to the conversion of the emitted radiation directly into electric power. This approach derives from the possibility to generate a current in a semiconductor due to the characteristics of the p-n junction. There are two possible methods to have current production from radioactive sources: the direct way, in which emitted particles generate the current in the junction, and the indirect one, in which emitted particles produce secondary effects that generate the current.

A typical example of the direct approach is the “betavoltaic effect” (Olsen, 1973). In this case a beta particle emitted by the radioactive source interacts with the depleted region of a p-n semiconductor junction. The ionized charges, electron-hole pairs, produced in such regions will be responsible for the generated current across the junction. In this way the two-step process will be avoided but at the same time an optimization of the beta source vs. semiconductor junction configuration is needed. In fact, only the energy released in the depleted region of the p-n junction will be converted into a current. The energy released in an electric contact or in the semiconductor inert materials will not produce charges that will take part in the electric generation. Moreover the ionized electron-hole pairs can undergo recombination that will strongly reduce the conversion efficiency. This effect could be around 30% of the global interaction efficiency and are normally unavoidable (Knoll, 2010). So, at the end the conversion efficiency can be of the order of 10% but normally only values around few percent are really achievable.

The indirect method relies on the fact that the energy released by particles emitted in the decays will produce photons inside luminescent materials. The number of generated photons is directly connected with the source activity and to the photon conversion efficiency of the luminescent material. If we look at typical luminescent plastic materials, normally 10,000 photons per MeV are produced as the consequence of the interaction of a beta particle (Knoll, 2010). Produced photons are typically in the ultraviolet/visible range of the electromagnetic spectrum and so they can be converted in a current thanks to photovoltaic cells. The conversion efficiency is not very large due to the two steps process: conversion of radioactive emissions to light and then conversion of generated light to current. It needs a careful optimization of the luminescent material in order to match the spectral response of the photovoltaic cell. Using this approach, an overall efficiency of few percent has been demonstrated, and further optimizations are possible.

Some interesting developments have recently been achieved using the charge produced by emitted particles, alphas or betas, to directly produce current. The emitted charged particles generate a voltage difference between the two “plates” of a capacitor, each one isolated from the other and from the environment, and a current will be produced when the two plates are shunted (Li et al., 2002). This very simple approach is interesting if we consider the use of a modern MEMS (Micro Electro Mechanical System) in which the charges produced by the radioactive sources will generates an oscillation of the MEMS structures and the generation of electrical power.

Glossary

Actinide The 15 chemical elements between actinium ($Z = 89$) and lawrencium ($Z = 103$) that include the naturally occurring radioactively unstable elements thorium ($Z = 90$) and uranium ($Z = 92$) as well as the artificially produced transuranics, such as plutonium ($Z = 94$) and californium ($Z = 98$), several of which can decay through spontaneous nuclear fission.

Fertile material A non-fissile material that can be converted to fissile material by neutron irradiation.

Fissile material Material that is fissionable by thermal neutrons.

Fissionable element Any element that can undergo fission, either spontaneously or by reaction with neutrons, photons, or charged particles.

MeV Million electron volts; 1 eV (eV) is a unit of energy that is equivalent to 1.6022×10^{-19} J.

Nuclide Species of atomic nucleus, characterized by the atomic number, Z and neutron number N .

Thermal neutrons Thermal neutrons have energies in the 0–0.5 eV range, corresponding to the equivalent Maxwell-Boltzmann kinetic energy for an ideal gas at the ambient (moderator) temperature.

Transuranic element Elements of the periodic table with atomic number larger than uranium. All are unstable.

History and introduction

The startling discovery of nuclear fission that ushered in the modern atomic age was the culmination of more than a decade's worth of focused investigation by a large community of chemists and physicists eager to understand the secrets of the atom. After the discovery of the neutron in 1932 and the development of the idea that nuclei are composed of collections of protons and neutrons held together against the long-range electrostatic repulsion of the positively charged protons by a strong, short-range nuclear force, many experiments and theoretical descriptions were developed to study and explain the structure of nuclei.

Enrico Fermi in Rome, Lise Meitner and her collaborators, Otto Hahn and Fritz Strassmann, in Berlin, among others, sought to produce new "transuranic" elements (heavier than uranium) through neutron bombardment. Meitner, Hahn, and Strassmann's results, using radiochemical techniques for particle identification, suggested they had found new elements in their experiments that were chemically similar to other known elements but the identities of these products were difficult to pinpoint (Meitner et al., 1937). When Meitner fled Germany to escape persecution by the Nazi regime, Hahn and Strassmann continued their investigations and stumbled upon the startling fact that one of the elements produced in their experiments was the relatively light element barium (Hahn and Strassmann, 1939). They shared their conclusions with Meitner before publication and she had the occasion to discuss them with her nephew, Otto Frisch, a physicist working on similar experiments at Niels Bohr's institute for theoretical physics in Copenhagen. Meitner proposed the idea that the liquid drop model of the nucleus could help explain their results and she and Frisch described the basic parameters of the idea shortly thereafter (Meitner and Frisch, 1939).

Fission comes from the Latin *fissio* "to split" and was first used to characterize biological cell division in the nineteenth century. Meitner and Frisch selected it as the perfect descriptor for the process by which a nucleus breaks up into two fragments of more or less equal mass. They worked out estimates for the energy available to these products from the difference in mass of the incoming and outgoing nuclei and the electrostatic repulsion of the products and discovered that the energy release was significant. The implications of this discovery were immediately apparent. Upon hearing the core idea of their manuscript from Frisch, Bohr is said to have exclaimed "Oh, what idiots we have been that we haven't seen that before. Of course this is exactly as it must be." Bohr was on his way to the United States to meet with collaborators and attend conferences and was able to work out the initial theoretical details of the fission process that he and collaborator John Wheeler refined into their seminal paper, The Mechanism of Nuclear Fission (Bohr and Wheeler, 1939).

Once it was known that fission could not only produce significant quantities of energy but also emitted additional neutrons that could themselves initiate fission and, possibly, establish a fission chain reaction, the race to harness this energy source was on. The start of the second world war both inhibited research and refocused it on applications that would support the war effort. Most notably, the application of nuclear fission for use as a weapon became the focus of the Manhattan Project in the United States (Cameron, 2021) that eventually led to the first deployment of nuclear weapons in Hiroshima and Nagasaki, Japan, in late 1945. The application of nuclear fission to energy production is discussed elsewhere in this volume. In the next sections, details of the fission process and its products are described.

The process of nuclear fission: Excitation and breakup

Heavy nuclei have a large positive electric charge due to their large atomic number, Z . The heaviest naturally occurring element, uranium, has an atomic number of $Z = 92$. This produces a large, long-range electric field that inhibits the close interaction of slow-moving nuclei and other positively charged particles. The neutron, on the other hand, having no net electric charge, is not repelled and has a high probability to interact with nuclei if they are brought together. Reactions between neutrons and nuclei can be set up experimentally, with energetic consequences. The left panel of Fig. 1 shows a schematic of the capture and excitation of the isotope ^{235}U by a bombarding low-energy neutron. The compound nucleus ^{236}U formed from this capture is in an excited state that allows it to decay by fissioning into two smaller mass fragments and one or more neutrons, accompanied by a significant release of energy. The product nuclei are themselves unstable and will decay through emissions of beta particles (electrons), gamma rays, and anti-neutrinos that carry away some of the energy, but the bulk of the energy released during this process goes into the kinetic energy of the fission fragments that are accelerated away from one another by their mutual electrostatic repulsion.

The nuclear breakup process can be understood as a consequence of the charged liquid-drop model of nuclear structure. It was Meitner who first intuited that this model, applied to an excited nucleus with severe spatial deformation, could cause the nucleus to break into two smaller charged drops because of their strong electrostatic repulsion (Meitner and Frisch, 1939). The right panel of Fig. 1 shows a schematic of the stages of fission from nearly spherical ground state to deformed excited states of various degrees of deformation, leading to the narrow neck between the two lobes that produces a strong electrostatic repulsion which drives the division of the nucleus into two smaller fragments.

The energy imparted to the fragments comes from the conversion of electrostatic potential energy to kinetic energy as the fragments separate. Fig. 2 shows a schematic of the total energy of the fragments at different stages of nuclear deformation adapted from Hodgson et al. (1997). In the ground state, the fragments are bound inside the nucleus with an energy corresponding to the sum of the masses of their constituents minus the binding energy that holds them together. The overall height of the barrier, E_b , represents the electric potential energy from the mutual repulsion of their constituent protons and is a measure of the energy available for release in the fission reaction. If the nucleus becomes excited, for example by absorbing a neutron and deforming as a result, the fragments may obtain enough energy, E_{ex} , to “climb over” the barrier and separate completely, releasing the barrier energy in the fission process.

For the example reaction illustrated in Fig. 1, the difference in mass between the bombarding neutron and its target ^{235}U and the compound nucleus of ^{236}U formed when the neutron is absorbed corresponds to an energy of 6.5 MeV. This slightly exceeds the excitation energy needed to overcome the barrier, allowing the fragments to separate through the fission process.

The masses of nuclei can be calculated in energy units using the semi-empirical mass formula (Napolitano, 2020), and the binding energy per nucleon is obtained by solving for the non-mass terms. As in Fig. 1 of Napolitano (2020), the binding energy per nucleon increases with mass number up to the elements near iron, where it has a value close to 8.5 MeV, then decreases with mass number. The decrease in binding energy for elements larger than iron means that energy is released when very heavy nuclei break apart. For fission reactions such as the example illustrated in Fig. 1, the compound nucleus of ^{236}U breaks up into two lighter

Fig. 1 (Left) A neutron bombards a nucleus of ^{235}U , which absorbs it and becomes excited. The excited nucleus of ^{236}U is unstable and splits into two lower mass nuclear fragments plus a few neutrons and gamma rays. (Right) Deformation of an excited nucleus during the stages of fission.

Fig. 2 Schematic of the potential barrier for a heavy nucleus as a function of the separation between two constituent fragment nuclei. Based on Figure 18.18 (page 401) from Hodgson PE, Gadioli E and Gadioli Erba E (1997) *Introductory Nuclear Physics*. Oxford University Press: New York.

mass fragments and the difference in mass between the initial and final states can be calculated directly or estimated from the binding energy curve by comparing the binding energy per nucleon for ^{235}U with that of the average fragment mass ($A = 118$). The result is approximately 200 MeV of energy that is liberated by this process, an extraordinary amount.

The products of nuclear fission

When a nucleus fissions, it does not typically fragment into equal mass products, although that is a possible outcome. More commonly the fragments are asymmetric, as seen in Fig. 3. The curves represent evaluated average yields of all the known nuclear fission products of ^{235}U , organized by mass number and tabulated for three different bombarding neutron energies: 0.025 eV (thermal), 500 keV (slow or epithermal) and 14 MeV (fast) by Chadwick et al. (2011). Thermal neutrons are so-called because those energies correspond to the equivalent Maxwell-Boltzmann kinetic energy for an ideal gas at the ambient temperature. The dashed lines indicate the masses of the fragments from the example illustrated in Fig. 1. These fission product nuclei are radioactively unstable and will further evolve through beta decay and gamma emission or delayed neutron evaporation to reach their most stable configurations.

In addition to the charged fragments of large mass that are emitted in the fission process, a small number of neutrons are also liberated through evaporation near the surface of the fissioning nucleus (prompt neutrons) and from the unstable fragments after they are released (delayed neutrons). These prompt and delayed neutrons carry away only a small fraction of the total energy but play a significant role in making nuclear fission a viable source of energy because they have the capacity to initiate further fissions within a sample of material. Fig. 4 shows the average number of neutrons emitted per fission, $\bar{\nu}$, for ^{233}U , ^{235}U , and ^{239}Pu as a function of neutron energy (Chadwick et al., 2011). Although the neutron yield grows with neutron energy above 1 MeV, the averages shown are typical for thermal and slow neutron-induced fission reactions.

Fig. 3 Mass distribution of fragments emitted from neutron-induced fission of ^{235}U as a function of mass number for three different incident neutron energies: thermal (0.025 eV), slow (500 keV) and fast (14 MeV). The curves represent evaluated average yields tabulated by Chadwick et al. (2011). Data from Chadwick MB, Herman M, Obložinský P et al. (2011) *ENDF/B-VII.1: Nuclear Data for Science and Technology: Cross Sections, Covariances, Fission Product Yields and Decay Data*. Nuclear Data Sheets 112, 2887. Fig. 5 Energy spectrum of outgoing neutrons from fission of ^{235}U induced by thermal neutrons on both linear (left) and logarithmic (right) energy scales. The data from Lajtai A, Kecskemeti J, Safar J, Dyachenko PP and Piksaikin VM (1985) Energy spectrum measurements of neutrons for energies 30 keV–4 MeV from thermal fission of main fuel elements. In: *Conference on Nuclear Data for Basic and Applied Science, Santa Fe, USA*, vol.1, p. 613.; Cranberg L, Frye G, Nereson N and Rosen L (1956) Fission neutron spectrum of ^{235}U . *Physical Review* 103: 662 [Retrieved from National Nuclear Data Center, Brookhaven National Laboratory, <https://www.nndc.bnl.gov/>] are compared to a Maxwellian function with a mean value of 1.95 MeV and the empirical Watt spectrum, Eq. (1) Curve from Watt BE (1952) Energy Spectrum of Neutrons from Thermal Fission of U235. *Physical Review* 87(6): 1037–1041.

The energy spectrum of the prompt neutrons from thermal neutron-induced fission of ^{235}U is shown in Fig. 5. The left panel shows the data on a linear energy scale while the right panel is logarithmic in energy. The data from Lajtai et al. (1985) and Cranberg et al. (1956) are compared to a Maxwellian function with mean energy of 1.95 MeV and the empirical Watt spectrum (Watt, 1952):

$$P(E) = 0.4865 \sinh(\sqrt{2E}) e^{-E} \quad (1)$$

In addition to the prompt neutrons emitted within $\sim 10^{-14}$ s of the fission process, the fission products themselves are highly unstable, neutron-rich nuclei that undergo further radioactive decays. This chain of reactions produces additional β -delayed neutrons that are capable of inducing further fission reactions. The time-scales for emission of these neutrons are driven by the β -decay chain half-lives and are typically grouped accordingly. Delayed neutrons play an important role in reactor design, discussed elsewhere in this volume. Table 1 summarizes the relative and total yield of delayed neutrons from neutron induced fission of ^{235}U , ^{238}U , and ^{239}Pu grouped by half-life (Koning et al., 2006).

While neutron absorption is the catalyst for fission, neutrons carry away only a small fraction of the total energy released during fission and constitute a small component of the overall momentum balance because of their small mass relative to the fragments.

The total energy released during fission, the so-called “Q-value” of the reaction, can be calculated from the difference in mass between the incoming and outgoing neutrons and nuclei, converted to energy units.

$$Q = \Delta mc^2 = [(m_U + m_n) - (m_{Te} + m_{Zr} + 3m_n)]c^2 \quad (2)$$

The right-hand side of Eq. (2) corresponds to the example illustrated in Fig. 1 and has a resulting value near 200 MeV that is shared among all of the products of the fission reaction, including those that arise from the radioactive decay of the unstable fragments.

Table 1 Delayed neutron yield by group half-life for neutron induced fission of ^{235}U , ^{238}U , and ^{239}Pu .

Group #	Group half-life (s)	Fractional delayed neutron group yield (ν_d/ν_t)		
		^{235}U (thermal)	^{238}U (fast)	^{239}Pu (thermal)
1	55.6	2.18×10^{-4}	1.39×10^{-4}	7.2×10^{-5}
2	24.5	1.023×10^{-3}	1.716×10^{-3}	5.33×10^{-4}
3	16.3	6.05×10^{-4}	6.19×10^{-4}	1.859×10^{-4}
4	5.21	1.31×10^{-3}	2.26×10^{-3}	4.1×10^{-4}
5	2.37	2.2×10^{-3}	4.85×10^{-3}	6.62×10^{-4}
6	1.04	6.0×10^{-4}	3.27×10^{-3}	1.836×10^{-4}
7	0.424	5.40×10^{-4}	2.11×10^{-3}	1.62×10^{-4}
8	0.195	1.52×10^{-4}	1.536×10^{-3}	4.16×10^{-5}
Total fractional yield (ν_d/ν_t)		6.65×10^{-3}	1.65×10^{-2}	2.25×10^{-3}
Total ν_d (per fission)		0.0162	0.0465	0.0065

Delayed neutron yields by group half-life for neutron induced fission of ^{235}U , ^{238}U , and ^{239}Pu .

Table 2 Distribution of energy among fission products.

Quantity	^{233}U (MeV)	^{235}U (MeV)	^{239}Pu (MeV)
Kinetic energy of fragments	168.22 ± 0.50	169.13 ± 0.49	175.55 ± 0.40
Kinetic energy of prompt neutrons	4.90 ± 0.10	4.84 ± 0.07	6.13 ± 0.10
Kinetic energy of delayed neutrons	0.0310 ± 0.0047	0.0074 ± 0.0011	0.0030 ± 0.0004
Kinetic energy of prompt gammas	7.72 ± 0.52	6.60 ± 0.50	6.74 ± 0.47
Kinetic energy of delayed gammas	5.01 ± 0.06	6.33 ± 0.05	5.17 ± 0.06
Energy of delayed betas	5.16 ± 0.06	6.50 ± 0.05	5.31 ± 0.06
Energy of neutrinos	6.93 ± 0.09	8.75 ± 0.07	7.14 ± 0.09
Total energy released per fission, Q	197.97 ± 0.21	202.16 ± 0.13	206.04 ± 1.18
Total energy less neutrino energy	191.04 ± 0.23	193.41 ± 0.15	198.90 ± 1.09

Components of energy released in fission for the actinides ^{233}U , ^{235}U , and ^{239}Pu .

Data from Chadwick MB, Herman M, Obložinský P et al. (2011) *ENDF/B-VII.1: Nuclear Data for Science and Technology: Cross Sections, Covariances, Fission Product Yields and Decay Data*. Nuclear Data Sheets 112, 2887. National Nuclear Data Center, Brookhaven National Laboratory. [Retrieved from: <https://www.nndc.bnl.gov/>].

Table 2 shows the distribution of energy among the various fission products for ^{233}U , ^{235}U , and ^{239}Pu tabulated by [Chadwick et al. \(2011\)](#), with approximately 85% going into the kinetic energy of the fragments themselves, while nearly 3% is carried by the neutrons, 6% by gammas, and the remaining 12% is distributed among the electron and neutrino products of the fragment beta decays. Note that the energy imparted to the neutrinos is not available because of their extremely low interaction probabilities. That waste energy exits a reactor never to be recovered.

When the fission chain reaction in a nuclear reactor is halted, the rate of fission drops but there remains significant residual thermal power (heat) produced from delayed radioactive decays of the fission products that continues for a significant amount of time. **Table 2** illustrates that as much as 13% of the energy from each fission contributes to this delayed heat output. The precise power curve after shutdown depends on the mixture of isotopes present and their respective half-lives. **Fig. 6** shows a typical decay heat power curve from the fission of ^{235}U (thermal), ^{238}U (fast), and ^{239}Pu (thermal) over time after reactor shutdown tabulated by [Shibata et al. \(2011\)](#). The integrated heat output from the residual decays is significant and is an important consideration in reactor design.

Fission probabilities

As shown in **Fig. 5**, the prompt neutrons emitted during fission have average energies in the fast region of neutron energy classification (> 1 MeV), where the probability of capture by and fission of another nucleus of ^{235}U is highly suppressed relative to that for thermal neutrons. The probability of neutron-induced fission is typically reported in terms of a “cross-section,” measured in barns (10^{-24} cm²), that characterizes the effective areal overlap of a neutron projectile impinging on a nuclear target. **Fig. 7** shows the evaluated average cross-sections for neutron-induced fission of ^{235}U and ^{238}U as a function of neutron energy for all available measured data tabulated by [Chadwick et al. \(2011\)](#). The thermal and fast neutron energy regions are identified by the dashed vertical lines. The region between these two boundaries exhibits significant structure, corresponding to resonance absorption of

neutrons into specific excited quantum states of the nucleus that are present at higher density for these energies. A comparison of Figs. 5 and 7 illustrates that the prompt neutrons from fission are not in the region where the fission cross-section is largest.

Both of the isotopes shown in Fig. 7 are present in naturally occurring uranium but at significantly different abundances, with ^{238}U at 99.2745% and ^{235}U at 0.72%. Notice that the cross section for thermal neutron induced fission of ^{238}U is seven orders of magnitude below that of ^{235}U and only becomes comparable in the fast region. This makes it a non-fissile material and may partly explain why fission was such a challenging discovery to make. Since the thermal neutrons and natural uranium used in the early experiments had such a low probability for fission and the idea that a nucleus could break up in this way was far outside the accepted understanding of nuclear physics at the time, it took imagination and insight to realize the obvious (Pearson, 2015). As noted by Nobel Laureate Emilio Segrè, “This is a tricky setup. Above all, it seems to me that the human mind sees only what it expects” (Segrè, 1989).

Spontaneous fission

In addition to fission induced by bombarding particles such as neutrons, photons, protons, and other charged particles, there are many actinides (thorium and beyond) that can undergo spontaneous fission. This process is a consequence of nuclear shell structure and the inherent deformation of neutron-rich heavy nuclei in their ground state. The result is a double-humped structure in the fission barrier of Fig. 2 that increases the chances that the fragments can quantum mechanically tunnel through the barrier and fission. One can predict the mean lifetime for spontaneous fission from the pairing term in the semi-empirical mass formula (Napolitano, 2020). The condition for spontaneous fission to be favorable occurs when the ratio of $Z^2/A > 47$, and the larger the value of this ratio,

the shorter the lifetime. Most nuclides that have a high branching ratio for spontaneous fission fall below this value ($Z^2/A = 38.1$ for ^{252}Cf). The discrepancy is due to the fact that nuclear shell effects, which are significant for the highest mass nuclei, are not well-described by the liquid drop model so the dependence on Z^2/A is only approximate (Krane, 1987).

Fig. 8 shows the high Z , N region of the chart of the nuclides, with the nuclides color-coded according to their largest nuclear decay branching ratio. Green boxes indicate those nuclides whose dominant decay mode is spontaneous fission. The vertical dashed lines correspond to the elements uranium and californium and the horizontal lines at constant neutron number show the known nuclides for these elements. While the dominant mode for ^{252}Cf (at the intersection of $Z = 98$ and $N = 154$) is via alpha decay, it has an appreciable branching ratio for spontaneous fission ($\sim 3\%$), making it a useful source of neutrons. Table 3 lists spontaneous fission characteristics of selected nuclides, including their neutron yields from Chadwick et al. (2011), Holden and Hoffman (2000), and Plompen et al. (2020).

The nuclides ^{233}U , ^{235}U , and ^{239}Pu are considered most useful for nuclear energy production because they are all fissile, have small spontaneous fission branching ratios, are relatively long lived, and have high thermal neutron cross sections. Although ^{233}U is not naturally present in uranium ore and ^{239}Pu is not naturally occurring, both can be created via neutron capture of the fertile materials ^{232}Th and ^{238}U , respectively, and thorium is three times more abundant than uranium.

Fig. 8 Chart of the neutron-rich heavy nuclides, color-coded according to their dominant decay mode. Those nuclides whose dominant decay mode is spontaneous fission are shown in green. Data from ENSDF database as of April 4, 2016. Version available at <http://www.nndc.bnl.gov/ensarchivals/>.

Table 3 Spontaneous fission characteristics for selected nuclides.

Nuclide	Half-life (years)	SF branching ratio (%)	SF half-life ^a (years)	Total neutron yield (per SF)	Calculated total neutron yield ($\text{g}^{-1} \text{s}^{-1}$)
^{232}Th	1.40×10^{10}	1.1×10^{-9}	1.2×10^{21}	1.50	7.07×10^{-8}
^{235}U	7.04×10^8	7.0×10^{-9}	1.0×10^{19}	1.87	1.04×10^{-5}
^{238}U	4.468×10^9	5.4×10^{-5}	8.2×10^{15}	2.00	1.35×10^{-2}
^{239}Pu	24,110	3×10^{-10}	8.0×10^{15}	2.32	1.59×10^{-2}
^{242}Cm	0.446	6.2×10^{-6}	7.0×10^6	2.528	1.96×10^7
^{244}Cm	18.1	1.4×10^{-4}	1.32×10^7	2.6875	1.10×10^7
^{250}Cm	8305	74	1.13×10^4	3.30 ^b	1.53×10^{10}
^{252}Cf	2.645	3.09	86.0	3.7676	2.28×10^{12}

Half-life, branching ratio, and neutron yields from spontaneous fission for a selection of nuclides.

Conclusion

Nuclear fission is a spectacular marvel of nature that allows us to harness the stored rest-mass energy of the heavy elements. The applications of this phenomenon to both weapons and energy production have been significant developments and drivers of human innovation, both destructive and beneficial, over the last century. Nuclear power, which currently provides 10% of the world's total electricity and 40% of the low-carbon electricity for advanced economies (Varro et al., 2019), has the potential to help us transform our energy systems away from fossil fuels so that we can mitigate the devastating effects of climate change while powering our modern world.

Glossary

Atomic number, Z The number of protons in a nucleus. The number of protons determines the number of electrons that attach to the nucleus, and hence the chemistry; thus each atomic number corresponds to a chemical element. Examples are $Z = 1$ for hydrogen, $Z = 6$ for carbon, $Z = 90$ for thorium and $Z = 92$ for uranium.

Compound nucleus The nucleus formed by combining a projectile and target nucleus. The compound nucleus may subsequently break up in different ways. For example, the compound nucleus formed by addition of a neutron to ^{235}U is ^{236}U , and subsequently it may fission or decay by gamma-ray emission.

Coolant Liquid or gas used to remove heat from the reactor core.

Coulomb repulsion Like charges to repel. In atomic nuclei Coulomb repulsion refers to the electrostatic repulsion between the positively charged protons, either within a given nucleus or between two nuclei in close proximity.

Cross section A measure of the likelihood that a nuclear reaction takes place when a projectile encounters a target nucleus, expressed in terms of the effective cross-sectional area presented by the target nucleus to the projectile. The units are therefore those of area, usually cm^2 or barns (b), where $1 \text{ b} = 10^{-24} \text{ cm}^2$. A larger cross section means a higher probability that a reaction takes place. The interaction of a given particle with a given nucleus can have several possible outcomes, each with a certain probability or cross section. The cross section is usually represented by the Greek letter sigma, often with a subscript to denote the particular outcome of the reaction. The total cross section is a sum of cross sections for each possible outcome. For example, the absorption of a neutron on ^{235}U can result in fission, or to the formation of ^{236}U , which can be designated as neutron capture. Thus $\sigma_a = \sigma_f + \sigma_c$, where σ_a is the absorption cross section, and σ_f and σ_c are the fission and capture cross sections, respectively.

Elastic scattering A collision between two particles in which their directions of motion and velocities can change but the total kinetic energy is conserved. In nuclear physics elastic scattering means that neither the projectile nor the target nucleus gains internal excitation energy as a result of the collision.

Electron volt, eV, keV, MeV A unit of energy. One electron volt (eV) is the energy gained by an electron accelerated by a potential difference of 1 V. $1 \text{ eV} = 1.602 \times 10^{-19} \text{ joule}$. The abbreviation eV can be prefaced by standard metric prefixes, so

meV indicates 10^{-3} electron volts (or millielectron volts), keV indicates 10^3 electron volts, and MeV indicates 10^6 electron volts (or megaelectron volts).

Fast neutrons Neutrons with an energy of the order of 1 MeV that are emitted during fission.

Fission fragments The two nuclei that result from the fission of a heavier nucleus.

Fuel Source of nuclear energy usually uranium or plutonium; it can contain fissile and fertile material.

Inelastic scattering A collision between two particles in which total kinetic energy is not conserved. In nuclear physics inelastic scattering means that either the projectile or the target nucleus, or both, gain internal excitation energy as a result of the collision.

Isobars Nuclei that have the same number of nucleons and hence the same mass number, A . The parent and daughter nuclei in beta decay are isobars.

Isotones Nuclei that have the same number of neutrons but differing numbers of protons (cf. isotopes).

Isotopes Nuclei that have the same number of protons but differing numbers of neutrons (cf. isotones). Isotopes are variants of the same chemical element.

Mass number, A The number of protons plus neutrons (i.e. the total number of nucleons) in an atomic nucleus. Thus the mass number is the sum of the proton or atomic number (Z) and the neutron number (N), $A = Z + N$.

Moderator Material in a thermal reactor that slows down fast neutrons, usually water, heavy water, or carbon in the form of graphite.

Multiplication factor k The number of fission neutrons in one generation of a chain-reaction divided by the number of fission neutrons in the preceding generation.

Neutron fluence The neutron flux integrated over a period of time. It can be described as the total number of neutrons passing through a unit area over a period of time, or as the total length travelled by all free neutrons per unit volume over a period of time. The fluence is usually expressed in the units of neutrons per square centimeter.

Neutron flux (ϕ) A measure of the intensity of the free neutrons in a reactor and their rate of flow. It is evaluated as a product of the number of neutrons per unit volume n and the neutron velocity v , $\phi = nv$ and is usually expressed in the units of neutrons per square centimeter per second. It can also be described as the number of neutrons passing through a unit area per unit time, or as the total length travelled by all free neutrons per unit volume per unit time.

Neutron number, N The number of neutrons in a nucleus. Each chemical element with a specified number of protons can exist as many isotopes that have different numbers of neutrons. The isotopes can be stable or radioactive. For example most of the hydrogen that exists in nature has a nucleus that consists of a single proton. However a small fraction of natural hydrogen is deuterium, which has one proton and one neutron in the nucleus. Tritium, with one proton and two neutrons, is a radioactive isotope of hydrogen. The element tin (chemical symbol Sn), with $Z = 50$, has the most stable isotopes.

Nucleon A proton or a neutron. Nucleon is a generic name for these constituents of the atomic nucleus.

Reactor core The part of the reactor containing the fuel, where fission takes place and heat is generated.

Reflector Material to help reflect neutrons back into the reactor core (often simply more moderator).

Scission The point during fission when the neck between the two nascent fission fragments breaks and the two fission fragments first separate.

Thermal neutrons Neutrons with an energy of the order of 0.025 eV (electron volt), which corresponds to room temperature (20°C). Fission-emitted neutrons can slow-down by successive scattering collisions with the moderator (and also some other core constituents) to nearly thermal equilibrium with the moderator nuclei. For comparison, 300°C corresponds to 0.049 eV.

Review of neutron-induced fission

Fission was introduced in the previous chapter (Klay, 2021). Here we give a descriptive review of the properties of fission with an emphasis on those relevant to sustaining a chain reaction. The following discussion will consider neutron-induced fission of ^{235}U , however most of the discussion is equally relevant for other fissile nuclei like ^{239}Pu and ^{233}U .

When ^{235}U captures a neutron it forms the compound nucleus ^{236}U in a highly excited state. The excitation energy comes from the fact that nucleons bind strongly as pairs; it is for this reason that the familiar fissile isotopes all have an odd number of neutrons. Even in its ground state, the ^{236}U nucleus is already deformed, having a shape like a rugby ball with its long axis about 30% longer than the diameter of its circular profile at the center. With the added excitation energy, the nucleus becomes free to explore new shapes, and the strong Coulomb repulsion of the protons favors even more extreme nuclear deformations, eventually splitting the nucleus into two fission fragments. The point at which the connection between the fission fragments breaks is called scission. The separated nuclei so formed are then pushed apart by their mutual Coulomb repulsion. About 200 MeV of energy is released, with typically about 85% of this energy appearing as kinetic energy of the two fission fragments.

The fission fragments have unequal masses. The heavier one has an atomic number near $A = 140$, and the other near $A = 95$. Until recently, the origin of the mass difference was thought to be directly related to the extra stability of the heavy fragment

near the doubly magic nuclide ^{132}Sn ($Z = 50$ and $N = 82$), however [Scamps and Simenel \(2018\)](#) have recently shown, on the basis of sophisticated theoretical calculations, that it is octupole correlations that determine the mass split. In more pictorial language, it is clear from representations of fission like those in [Fig. 1](#) that the necking process forces the precursors of the fission fragments to take a pear (octupole) shape. The nuclear shell structure dictates that nuclei near $A = 140$ with 52–56 protons and 84–88 neutrons can acquire a pear-shaped deformation at little or no cost in energy, and it is this process that drives the asymmetry of the fission fragments. Obviously, if one fragment has about 140 nucleons, the other must have the remainder.

The fission fragments are neutron rich—that is they have more neutrons than the stable isotopes of the element. For example, say ^{236}U splits into $^{136}\text{Te} + ^{100}\text{Zr}$, the neutron/proton ratios for these three nuclei are $144/92 = 1.57$, $84/52 = 1.62$, and $60/40 = 1.50$, respectively. In contrast, the heaviest stable isotope of tellurium is ^{130}Te with $78/52 = 1.50$ and the heaviest stable isotope of zirconium is ^{96}Zr with $56/40 = 1.40$. The fission fragments are not only neutron-rich, but they have internal excitation energy, some of which is released by emitting neutrons. These neutrons from fission are emitted almost immediately after scission by the fission fragments and take about 5 MeV of the 200 MeV released. For thermal-neutron-induced fission of ^{235}U there are on average just under 2.5 neutrons per fission. The number of emitted neutrons is well described by a Gaussian distribution with a standard deviation close to unity. Thus the probability of emission is about 30% each for 2- and 3-neutron emission; for 1- and 4-neutron emission, the probability is about 15%. Emission of 1–4 neutrons therefore accounts for about 90% of the fission events. The fact that there are on average several neutrons emitted per fission enables the chain reaction.

About 10% of the energy from fission is held as binding energy in the neutron-rich fragments, and this energy is gradually released through beta decay. Neutrons are converted to protons, releasing beta particles (and antineutrinos) until a stable isotope with the same mass number is reached. In a few quite rare cases, the beta decay parent populates a highly-excited state in the daughter that then emits a neutron. This process gives rise to a beta-delayed component in the neutrons resulting from fission. The fraction of neutrons per fission with delayed emission is usually denoted as β . Although β is small ($< 1\%$), these beta-delayed neutrons help control the chain reaction in a reactor.

Fission chain reaction

The concept of the nuclear chain reaction is illustrated in [Fig. 2](#). An initial neutron induces the fission on a fissile nucleus (^{235}U in this example), which results in the emission of two (or more) neutrons. If two of the emitted neutrons in turn induce a fission producing another two neutrons, the number of fissions will double with every “generation.” The number of fissions and the energy release grows exponentially and rapidly if the process remains unchecked, resulting in the explosive power of an atomic bomb. To achieve this explosive potential requires highly pure fissile material (^{235}U or ^{239}Pu).

The fission rate R is determined by the product of the number of ^{235}U nuclei present N_{235} , the fission cross section σ_f , and the neutron flux, ϕ : $R = N_{235}\sigma_f\phi$. Note that the neutron flux determines the fission rate at a particular point in time, but the fission rate then determines how the neutron flux will develop with time.

For a nuclear reactor, a steady state is required. The rate of production of neutrons must balance the rate at which neutrons are being lost and subsequent fissions are being induced. On average only one of the neutrons that results from fission can be allowed to induce another fission event. Such a self-sustaining chain reaction can be achieved with low-enriched or natural uranium when it is properly mixed with a neutron moderator, or with uranium enriched in ^{235}U to higher than about 12% without the use of a moderator.

The condition in which the rate of fission is held steady in a chain reaction is called criticality: the number of neutrons in each generation is the same. In reactor theory, the multiplication factor is defined as $k = (\text{number of neutrons in current generation})/(\text{number of neutrons in the previous generation})$. Thus, the equilibrium condition is $k = 1$. If $k < 1$, the reactor is subcritical and cannot sustain the chain reaction. If $k > 1$, the reactor is supercritical and, if not checked, a dangerous runaway condition can result.

Fig. 1 Representation of the fission process in which a heavy nucleus divides into two. Elongation, neck formation and scission are indicated. For spontaneous and thermal-neutron induced fission there is an asymmetry in the fragment masses; one is near $A = 95$ and one is near $A = 140$. These images are artistic representations of fission based on microscopic calculations. Picture credit: Cedric Simenel.

Fig. 2 Chain reaction by neutron-induced fission of ^{235}U .

A further distinction can be made between a reactor being prompt supercritical or delayed supercritical. The small beta-delayed component in the neutrons resulting from fission, which delays the release of neutrons by seconds to minutes, was noted above. A reactor is prompt supercritical if $k > 1$ without any contribution from the delayed neutrons, i.e. if $k > 1 + \beta$. It is delayed supercritical if $k > 1$ solely due to the delayed neutrons, i.e. if $1 < k < 1 + \beta$. Reactors are operated in the delayed supercritical state so that they can be safely controlled by adjustment of the amount of neutron-absorbing material in the core, such as by mechanical movement of control rods.

The chain reaction and the first human-made nuclear reactor

Leo Szilard in September 1933 is generally credited with being the first person to seriously consider a nuclear chain reaction as a means of releasing energy. He was reacting to a newspaper report of Lord Rutherford's statement that anyone who looked for a source of power in the transformation of atoms was talking moonshine. Szilard's insight came after the discovery of the neutron but before the discovery of fission. It occurred to him that neutrons would be more likely able to sustain a chain reaction because they are not charged and can readily pass through a solid material until they encounter a nucleus with which they can interact and induce a nuclear reaction. He realized that if one neutron could initiate some kind of nuclear reaction that led to the release of two neutrons, there was a good chance that one of these neutrons could initiate another reaction, in turn releasing another two neutrons. Such a process would be exothermic (i.e. release energy) and industrial power and/or nuclear weapons could be possible.

The discovery of fission is often marked by the publication of Lise Meitner and Otto Frisch in *Nature* on February 11, 1939 entitled "Disintegration of Uranium by Neutrons: a New Type of Nuclear Reaction" (Meitner and Frisch, 1939). In fact, Meitner and Frisch were re-interpreting experiments by Hahn and Stassmann (1939) in Berlin who did not know how to explain the appearance of the element barium in a sample of uranium they bombarded with neutrons. Some years previously Fermi had performed similar experiments in Rome but had mistakenly interpreted the products of the bombardment of uranium by neutrons as heavier rather than lighter elements (Fermi et al., 1934). Meitner and Frisch realized that if the uranium nucleus was excited and considered as a charged liquid drop, it would be energetically favorable for it to split into two roughly equal pieces. They estimated that the energy release would be about 200 MeV. In the same volume of the journal *Nature*, Bohr (1939) commented on the mechanism of fission, mentioning the factors that affect the stability of a heavy nucleus considered as a charged liquid drop. Frederic Joliot soon afterward

proved the fission hypothesis and realized that neutrons must be emitted in the process (Von Halban et al., 1939). Three patents were taken out in early May 1939, describing a device for energy production, a method for stabilizing a device for energy production, and a method for perfecting explosive charges (an atomic bomb).

The first human-made self-sustaining nuclear reaction was demonstrated by Enrico Fermi and co-workers at the University of Chicago on December 2, 1942. Designated CP-1 (Chicago Pile 1), this reactor consisted of about 40 tons of natural uranium, including lumps of metal and oxide, in a matrix of about 385 tons of graphite. The graphite blocks, which served as moderator and reflector, were stacked in a neat cubic structure. With about 2 kW of power, ambient air cooling was sufficient. There was no shielding or containment. This experimental reactor was part of the Manhattan project. Already plans were in place for the full scale Hanford reactors to make plutonium. The purpose of CP-1 was to measure the so-called multiplication factor or k -value of the reactor, and hence inform the final design of the Hanford reactors. (A more detailed discussion of the multiplication factor is given below.)

Detailed accounts of events on December 2, 1942 have been given elsewhere (e.g. Rhodes, 1986, Hewlett and Anderssen, 1962). In short, the reactor was kept from going critical during assembly by including rods of cadmium, a known strong neutron absorber, among the graphite blocks. To bring the pile to criticality—the self-sustaining reaction conditions—the cadmium rods were gradually removed while the neutron count rate (proportional to the flux) was monitored. This process of removing control rods and monitoring the neutron count rate continued through the morning, and included some safety tests. There was an automatic safety system to drop a control rod into the core if the neutron count rate (flux) rose too high. This system tripped because the threshold was set too low and the reactor was shut down while Fermi went for lunch. Testing and pursuit of the sustained chain reaction resumed at 2 pm. The reactor finally went critical at 3:35 pm and operated for 28 min before being shut down. It was determined that the multiplication factor was $k = 1.0006$.

CP-1 was experimented with for a few months before being dismantled and then revamped as Chicago Pile-2 (CP-2) on a new site and with new features such as radiation shielding, a small laboratory on top of the pile for experiments using neutrons from the reactor core, and a face with ports that allowed materials to be inserted into the core for irradiation. CP-2 had a thermal power level of 10 kW and ran for over a decade.

The achievements and outcomes from CP-1 were manifold. It demonstrated a controlled fission chain reaction and the production of a neutron flux for experiments and plutonium production. From the culmination of extensive experimental and theoretical studies, it established the foundations of nuclear reactor theory and measured the multiplication factor, which was difficult to calculate precisely at the time. As such, it provided essential input data for the design of larger-scale reactor projects already under construction in the Manhattan project, namely the X-10 experimental reactor at Oak Ridge National Laboratory and the Hanford reactors for plutonium production. Much later (in May 1955) a patent for an inhomogeneous nuclear reactor was issued to Fermi and Szilard.

CP-1 and Fermi reactor theory

CP-1 validated what is now known as the *Fermi reactor theory* (Fermi, 1947; Esposito and Pisanti, 2010). In this section CP-1 is discussed in terms of the concepts of that theory as relates to sustaining the chain reaction.

Achieving criticality—Requirements

At the time of CP-1, only natural uranium was available. Natural uranium contains only 0.72% fissile ^{235}U with the remaining 99.28% being fertile ^{238}U (Shusterman, 2021). To achieve criticality and sustain the chain reaction in a reactor using natural uranium as fuel was a challenging technical problem. The requirements were that:

- (i) There must be a high probability that fission results when a neutron is absorbed in the fuel (i.e. the natural uranium). Neutron absorptions in the fuel that do not result in fission must also be minimized.
- (ii) Neutron absorption by materials other than the fuel in the reactor must be minimized.
- (iii) The escape of neutrons from the reactor core must be minimized. In other words, the reactor must be of sufficient physical size.

The neutron cycle and reactor theory—Fermi's four-factor formula

These requirements for establishing a stable chain reaction in a reactor can be discussed in terms of a neutron cycle. It can be considered to begin with a specified number of thermal neutrons being absorbed in the fuel and producing a new generation of fission or fast neutrons. The neutron cycle follows the fate of these fast neutrons as they interact with the fuel, slow in the moderator, and eventually interact with the fuel as thermal neutrons to initiate a new cycle (or generation).

As described above, the multiplication factor is defined as $k = (\text{number of neutrons in current generation})/(\text{number of neutrons in the previous generation})$. The Fermi four-factor formula for k_{∞} , the multiplication factor for a reactor with an idealized infinite sized core that does not lose neutrons out of the core, is

$$k_{\infty} = \eta \epsilon p f,$$

where η is the number of neutrons produced by fission from the absorption of one neutron in the fuel, ϵ is the fast fission factor, p is the resonance escape probability, and f is the thermal utilization factor. The following discussion describes these quantities in relation to CP-1.

Increased fission probability through moderation

The first requirement for a sustained chain reaction is that a sufficient number of neutrons must result from the absorption of a neutron in the fuel. In order to achieve a chain reaction, the probability of fission following the absorption of a neutron must be high. The probability that fission results when a fast neutron interacts with natural uranium fuel is too low to establish a fission chain reaction. This probability can be increased by enriching the fuel in ^{235}U above the natural level of 0.72%; however, this option was not available for the first reactor in 1942.

Nature, however, gives an alternative way to increase the probability of inducing fission in natural uranium. The cross section (probability) for neutron-induced fission of ^{235}U increases by about a factor of 600 if the fast neutrons from fission (their energy is about 1 MeV or 10^6 eV) are slowed to “thermal” energies (0.025 eV or 2.5×10^{-8} MeV). This enhancement in the fission cross section compensates for the low abundance of ^{235}U in natural uranium. A *moderator* having low probability for neutron absorption must be introduced to slow the fast neutrons to thermal energies. The moderator in CP-1 was carbon in the form of high purity graphite.

While the above discussion distills the key points, the viability of a fast versus a thermal reactor is more subtle. It depends on the relative probabilities of the alternative outcomes of a neutron encounter with a uranium nucleus in the fuel (i.e. for both ^{235}U and ^{238}U). The important processes are fission, capture leading to ^{236}U or ^{239}U , and scattering (especially inelastic scattering at energies near 1 MeV). The total cross section is essentially the sum of the fission, capture and scattering cross sections.

The cross sections for neutron-induced reactions on ^{235}U and ^{238}U are shown in Figs. 3 and 4, respectively. Also indicated is the distribution of fast neutrons from the fission of ^{235}U , which peaks below 1 MeV or 10^6 eV.

For fast neutrons encountering a uranium nucleus, the most likely outcome—by an order of magnitude or more for ^{238}U —is that the neutron will scatter and lose energy. It will be noted below that neutrons lose little energy in elastic collisions with uranium nuclei. However for neutron energies near 1 MeV the inelastic scattering cross section dominates and scattering with loss of energy is dominant.

Once the neutron energy drops below 1 MeV, the fission cross section for ^{238}U becomes essentially zero while the capture cross section grows. It is this combination of features in the scattering, capture and fission cross sections of ^{238}U that make a fast reactor impossible with natural uranium. In contrast, the cross section for fast-neutron fission of ^{235}U remains of the order of 1 b, but the ^{235}U content of natural uranium is too small to compensate for the inadequate neutron production and strong absorption of neutrons by ^{238}U .

The 600-fold enhancement in the fission cross section for ^{235}U at thermal energies leads to an effective cross section of about 4.2 b for thermal-neutron induced fission in natural uranium. The (parasitic) neutron-capture cross sections leading to ^{236}U and ^{239}U shown in Figs. 3 and 4 are also increased, but the effective cross section of 3.4 b at 0.025 eV, mainly due to capture on the ^{238}U , is sufficiently small. In contrast to the adverse role of scattering at higher energies, it is not important at thermal energies,

Fig. 3 Cross sections for neutron-induced reactions on ^{235}U as a function of energy. Fission is designated (n,f), capture (n, γ), and scattering (n,n'). The inelastic scattering contribution to the total scattering cross section is also indicated. The cross-section scale is on the left. The probability distribution of neutron energies that results from fission of ^{235}U is also indicated with its scale on the right.

Fig. 4 Similar to Fig. 3 but for neutron-induced reactions on ^{238}U .

because thermal neutrons are (by definition) in thermal equilibrium with their surroundings. For each thermal neutron absorbed in natural uranium about 1.35 are produced on average. Criticality can thus be achieved with natural uranium at thermal energies.

The choice of carbon as moderator for CP-1

The moderation process slows fast neutrons with energies of the order of 1 MeV to thermal energies, usually specified as 0.025 eV, which is the energy equivalent to room temperature. The moderation process is based on the elastic scattering of neutrons from the nuclei of the moderator. In other words, the neutrons lose kinetic energy by imparting kinetic energy to the nuclei of the moderator. A good moderating material is one for which a neutron:

- (i) loses a large fraction of its energy in a single collision, which “speeds up” the moderation process,
- (ii) has a high probability of scattering off the moderator nuclei, i.e. the elastic scattering cross section should be high,
- (iii) has a low probability of being absorbed by the moderator, i.e. the absorption cross section should be low.

From the point of view of neutron energy-loss per collision, the lower the atomic mass of the moderator, the better. In terms of elastic collisions, hydrogen is best whereas uranium is very poor. The hydrogen in ordinary water is suitable as a moderator in this respect, but Fermi found in early experiments that it absorbs too many neutrons to be used in a reactor with natural uranium as fuel. Fermi did not have enriched uranium available, so light water was not a viable option for CP-1, or for the early reactors fuelled by natural uranium that followed. Szilard suggested to Fermi in July 1939 that carbon or possibly heavy water might be suitable alternatives.

Heavy water, D_2O , which replaces the hydrogen in ordinary water with deuterium (the isotope of hydrogen with one proton and one neutron) is an excellent moderator because deuterium has a low atomic number and it does not absorb neutrons. However, deuterium is only 0.015% of naturally occurring hydrogen. It was not a viable choice for the first reactor because it was both difficult to separate from ordinary hydrogen and needed in large quantities.

Carbon in the form of graphite then became the best choice for the moderator. It was much more readily available than D_2O , and although not as efficient at slowing neutrons as hydrogen or deuterium per elastic collision, the probability of absorbing neutrons was found by Fermi and his group to be sufficiently small as to allow the successful construction of a reactor using natural uranium as fuel and carbon as moderator.

Beryllium was also considered as a moderator. A.H. Compton argued that it not only has the required low atomic weight, but also would add (via $(n,2n)$ reactions) rather than remove neutrons (Hewlett and Anderson, 1962). Experiments proved it to be a good moderator but graphite was more readily available.

As will be discussed below, one engineering consequence of the use of graphite is that a heterogeneous reactor core is required. The resonance escape probability for natural uranium homogeneously distributed through a matrix of graphite is too small to achieve criticality.

The number of neutrons from fission

In the four-factor formula, η is the number of (fast) neutrons produced by the absorption of one thermal neutron in the fuel, including both the fissile and fertile isotopes present. In Fermi’s CP-1 reactor the fuel was natural uranium, which is 0.72% fissile ^{235}U and 99.28% fertile ^{238}U . Only the fissile ^{235}U can undergo thermal-neutron induced fission, releasing energy and neutrons.

Some of the thermal neutrons can be absorbed by the fuel and not result in fission. An important process is neutron-capture on ^{238}U (the majority of the fuel) to form ^{239}U , which then undergoes two beta decays to form fissile ^{239}Pu . This process of converting fertile material to fissile material is discussed below.

The average number of neutrons per thermal-neutron induced fission of ^{235}U is $\nu = 2.44$, however $\eta < \nu$ even for pure ^{235}U because neutrons can be absorbed without causing fission. Denoting the thermal fission cross section as σ_f and the total absorption cross section as $\sigma_a = \sigma_f + \sigma_c$, where σ_c is the capture cross section, gives $\eta = \nu \frac{\sigma_f}{\sigma_a} = \nu \left(\frac{\sigma_f}{\sigma_f + \sigma_c} \right)$. Evaluating the cross sections for pure ^{235}U at 0.025 eV from Fig. 3 gives $\eta = 2.08$ fast neutrons per fission. Essentially the same value is obtained for an average over the Maxwell-Boltzmann distribution, whether at room temperature or 300 °C.

For natural uranium $\eta = 1.36$. Because η is so close to unity, achieving criticality with natural uranium requires attention to the reactor design to minimize the non-fission absorption of neutrons in the core, and the loss of neutrons from the core.

In addition to the neutrons produced by thermal fission, some neutrons can be produced by fission of both ^{235}U and ^{238}U induced by fast neutrons (see Figs. 3 and 4). The fast fission factor ϵ accounts for these fast fission neutrons. The physical size, shape and chemical form of the fuel determines the probability that a fast neutron can induce a fast fission before slowing-down to below the fast fission threshold. It is a relatively small effect. Typically, $\epsilon \approx 1.03$ for a reactor fuelled with natural uranium; the contribution from ^{238}U is dominant.

Minimizing neutron absorption—Resonance escape probability

Neutron absorption by materials other than the fuel in the reactor must be minimized. As a first approximation, the reactor can be considered to consist only of the fuel and the moderator. In addition, cadmium rods, which strongly absorb neutrons, were included in the core of CP-1 to control the chain reaction and prevent the reactor from going critical in an uncontrolled fashion. Criticality was approached steadily by gradually withdrawing the cadmium rods. Carbon (in the form of graphite) was the chosen moderator because it can slow neutrons with little absorption.

During the moderation process there is a critical range of neutron energies where the probability of the neutron being absorbed in the ^{238}U (which is the dominant component of the fuel) becomes very high. This is the region between 10 and 1000 eV where there are many sharp peaks called resonances in the neutron capture cross section (see Figs. 3 and 4). Resonances occur when the neutron energy is matched to form an individual excited quantum state in the compound nucleus, which makes the capture particularly favorable. It is the resonant absorption of neutrons that make it impossible to achieve criticality with a homogeneous mixture of graphite and natural uranium for which $k \approx 0.8$.

For the design of a thermal reactor operating on natural or low-enrichment uranium, it is essential to minimize the resonant absorption of neutrons on ^{238}U , the dominant component of the fuel. In other words, the resonant escape probability, p , must be maximized.

The solution is to build an inhomogeneous (also referred to as a heterogenous) reactor, as was CP-1. In an inhomogeneous reactor the fuel is not uniformly distributed through the moderator but is contained in rods, lumps, or sheets. The dimensions and geometry of the fuel and moderator are chosen so that the fast neutrons from fission in the fuel have a high probability of leaving the fuel at high energy (above the energy regime where resonances occur in the ^{238}U neutron-capture cross section) and getting into the moderator where they can be slowed to thermal energies before diffusing back into the fuel where they have a high probability of initiating another fission. Thus the physical geometry of the reactor is designed to reduce the probability that a neutron is in the fuel when its energy is in the resonance region and thereby the *resonance escape probability* is increased.

It is worth noting that the moderation process takes about a microsecond, whereas the moderated neutrons at thermal energies typically diffuse through the core for a thousand times longer (about a millisecond) before being absorbed (Krane, 1988).

Due to the complexity of the cross sections as a function of energy in the resonance region, coupled with non-uniform (inhomogeneous) geometry of fuel and moderator material, which also affects the spatial and energy dependence of the neutron density, a manual calculation of the resonance escape probability is extremely difficult. Today it can be done with the benefit of detailed nuclear data and sophisticated computer codes, but such were not available in 1942. An experimental measurement of the resonance escape probability was an important outcome of CP-1.

Thermal utilization—The fate of thermal neutrons

The final stage of the neutron cycle concerns the fate of the thermal neutrons in the core. The thermal utilization factor, f , is the fraction of the thermal neutrons absorbed in the fuel relative to the total neutron absorption in the core. In order to achieve criticality, absorption in non-fuel components must be minimized. Comparing homogeneous and inhomogeneous reactors, the thermal utilization factor is reduced in an inhomogeneous reactor, but the gain in the resonance escape probability is greater. CP-1 demonstrated that a chain reaction can be established and maintained in an inhomogeneous reactor with natural uranium as fuel and graphite as the moderator.

Leakage—Minimizing loss of neutrons from the core

The four-factor formula for k_∞ ignores the loss of neutrons from the core of the reactor. Two strategies were available to reduce the loss of neutron from the core of CP-1. First, the escape of neutrons from the reactor core becomes less important if the core size is

increased. The critical size of the core can be determined by use of the reactor equation (Tsvetkov, 2021; Duderstadt and Hamilton, 1976; Lamarsh and Baratta, 2001; Lilley, 2001), also developed as part of the Fermi reactor theory. Second, the escape of neutrons from the reactor core can be minimized by use of a reflector, which physically is often simply extra moderator material.

It is worth noting that a reflector in a reactor does not reflect neutrons in the way that a mirror reflects light, where one pictures a ray of light bouncing off the surface of the mirror like a ball off a wall. A more accurate picture of the reflector in a reactor is that it provides a medium in which the neutrons can be thermalized (if they are not already at thermal energies), and once thermalized can bounce around, colliding at random with the reflector atoms, with a chance of eventually diffusing back into the reactor core. This process is not as efficient as the reflection of light by a mirror, but without the reflector, any neutron that leaves the reactor core will continue in a straight line path out of the reactor core, whereas with a reflector, some neutrons will diffuse back into the core. A small fraction of the fast neutrons that leak to the reflector may scatter back to the core even before they thermalize. Often the reflector is simply additional moderator material surrounding the core. Thus in CP-1 the graphite matrix served as both moderator and reflector.

The natural nuclear fission reactors of Oklo, Gabon

In 1956 Paul Kuroda used the Fermi reactor theory (the four-factor formula) to show that in the early history of the Earth a uranium deposit of appropriate dimensions with a suitable water content could easily sustain a chain reaction. Because the half-lives of ^{235}U ($T_{1/2} = 7.04 \times 10^8$ years) and ^{238}U ($T_{1/2} = 4.47 \times 10^9$ years) differ, the ^{235}U content in natural uranium is increased on geological time scales into the past. Today natural uranium contains 0.72% ^{235}U , whereas 1 billion years ago (10^9 years) the ^{235}U content was about 1.6% and 2 billion years ago it was near 4%, comparable to the enrichment used in a modern light-water moderated (and cooled) power reactor.

Kuroda's work was largely forgotten until 1972 when it was discovered that the ^{235}U content of some uranium samples from mines in the Oklo region in Gabon, Africa, was significantly below the usual 0.72%. This evidence of missing fissile ^{235}U came as a surprise and was perplexing at first, until the predictions of Kuroda (Kuroda, 1956, 1960) and the speculations of others (Wetherill and Inghram, 1953) were recalled. It then became evident that the ^{235}U content of the deposit was depleted because it had been consumed in an ancient natural nuclear reactor, very much along the lines of those predicted by Kuroda (Meshik, 2005).

Description of the Oklo reactors

In total 16 reactor zones were identified in the Oklo region and a seventeenth in nearby Bangombé (de Laeter and Hidaka, 2007). Unfortunately all but the Bangombé reactor have been mined out. However extensive studies of isotope ratios and other properties of the reactor zones have been performed that allow us to build up a rather complete picture of their operation.

The reactor zones range in depth from near surface (less than 100 m) to more than 400 m underground. Those nearer the surface have clearly been subject to weathering, while the deeper ones are considered to have better preserved the fission products and other consequences of the reactor operation. The reactors were typically within lens-shaped conglomerates with length and width of order 10 m and up to about 0.8 m thick. These dimensions are close to Kuroda's estimates, including that a thickness greater than "a few feet" is needed to achieve criticality. The reactors themselves were in uranium-rich zones of the deposit, consisting of uraninite (up to 60% uranium).

The requirements for a natural reactor

There are several requirements for a natural reactor to achieve criticality:

1. The uranium ore body must have high uranium content and appropriate dimensions and geometry; for example, it should be at least around 0.7 m thick. These requirements for the deposit ensure, first, that the infinite multiplication factor will exceed unity, and second, that the leakage of neutrons from the reactor zone is limited. Note that whereas the fissile material is ^{235}U , it is ^{238}U that provides the neutrons from spontaneous fission to initiate the reaction. In particular, for ^{238}U the spontaneous fission partial half-life is $T_{1/2}(\text{SF}) = 8.2 \times 10^{15}$ years, much shorter than for ^{235}U for which $T_{1/2}(\text{SF}) = 1.0 \times 10^{19}$ years. The dominant decay mode for both uranium isotopes is alpha decay, for which ^{235}U has the shorter partial half-life. Additional neutrons can be produced by alpha-particle induced reactions on light elements that may be present.
2. The uranium must contain a significant amount of fissionable ^{235}U . The ^{235}U level of 0.72% today in natural uranium is not sufficient to allow a natural reactor to operate in a uranium deposit. Natural reactors can therefore only have existed on Earth in the distant past.
3. A moderator is required to slow the fission-produced neutrons. This is most likely to be water in a natural reactor.
4. There must be limited quantities of neutron-absorbing elements in the deposit that would inhibit the chain reaction.

None of these requirements is exceptional for an ancient uranium deposit, nor are the geological features of the Oklo deposits unique when considered individually. Soon after the Oklo reactors were discovered, there was therefore some expectation that other ancient reactors would be discovered in other uranium deposits around the world (Maurette 1976; Cowan, 1976). However none have been found. For example, a search for fossil reactors in several mine sites in the Alligator River Uranium Field in Australia

found no evidence of a sustained chain reaction. The inferred low neutron fluence at Narbarlek, a site considered a good candidate for a natural reactor, was consistent with neutron production from spontaneous fission of ^{238}U , (α, n) reactions, and some slow-neutron induced fission of ^{235}U (Maas and McCulloch, 1990).

Although it is possible that some ancient reactors have been mined out without being noticed, it remains a puzzle as to why no other fossil reactors have been found.

Nuclear forensics of the ancient reactors and their operation: Isotopic analysis of fission fragments

Much of what we now know about the Oklo reactors has been determined by careful studies of the isotope ratios of elements created as fission fragments during the operation of the reactor (de Laeter and Hidaka 2007). The measurement method is known as mass spectrometry. Mass spectrometry covers a range of techniques which measure the relative abundances of the different isotopes of a given element in a sample. For example, we know that the consumption of ^{235}U in the Oklo deposits was indeed due to nuclear fission because the isotopic ratios of several rare earth elements collected from the reactor zone are very different from those normally found in nature but reflect those that result from fission.

The example of the neodymium isotopes is clear and instructive: In natural neodymium, the most abundant isotope is ^{142}Nd (27.13%), but this isotope cannot be produced in fission because the decay of the neutron-rich mass 142 isobars from fission terminates on stable ^{142}Ce , which blocks the production of ^{142}Nd . In contrast, the most abundant neodymium isotope from fission is ^{143}Nd . Samples of Nd from Oklo ore show a very low fraction of ^{142}Nd ($\sim 1\%$) and an isotopic distribution that is closer to that of fission-produced Nd than natural Nd. The ^{142}Nd in the ore can be assumed to represent the natural fraction, not originating from fission. When it is used to correct the isotope ratios of the ore for a small background of Nd from natural sources, what remains closely matches the distribution produced by the fission of ^{235}U .

The age of the reactors has also been determined by several radioactive dating procedures based on mass and isotope ratios, with general agreement that the age of the Oklo deposit is approximately 2×10^9 (or 2 billion) years. Thus, on the geological time scale, the chain reactions commenced shortly after the formation of the deposits. At the time of the formation of the Earth, the ^{235}U abundance was about 17%. It is natural therefore to ask why no evidence has been found of even older natural reactors. The answer is in the geology and biological history of Earth: Uranium ore deposits did not form until around 2.2 billion years ago, linked to the sudden increase of oxygen in the atmosphere and water due to the activity of cyanobacteria, which in turn affected the solubility of uranium oxides and enabled the deposition of high-grade uranium ores.

Other nuclear properties of the reactors investigated include the average neutron flux, the average power, the pulsed nature of the reactor operation, the total time the reactors operated and even the average reactor operating temperature. These studies make use of the fact that the distribution of neutron-rich fission products is known, as are the lifetimes of the fission fragments as they decay toward the valley of stability. Moreover, some fission products, as well as some of the isotopes in the surrounding clay and rock, are strong neutron absorbers, whereas others are not. This detailed knowledge of nuclear properties, together with extensive measurements on the isotopic residues in and near the reactor zones, has made it possible to build up a rather complete description of the reactors.

The reactors operated for some hundreds of thousands of years in a self-regulating pulsed mode. The uranium deposits in the absence of water were subcritical. However when water permeated the reactor zone it acted as a moderator and the reactors became supercritical. The heat generated then heated and vaporized the water, driving it off and returning the reactor zone to a subcritical state. By careful analysis of xenon isotope ratios, and understanding the properties of their precursors in the mass-decay chains, it was possible to deduce that the critical or heating period was about 30 min whereas the cooling or subcritical time was about 2.5 h, the whole cycle being about 3 h. Eventually, through the consumption of ^{235}U by fission as well as its normal radioactive decay, the ^{235}U enrichment level in the deposit dropped below the level at which criticality could be achieved, and the reactors ceased to operate.

What we learn from the Oklo fossil reactors

The Oklo reactors have provided extensive opportunities to study the fascinating phenomenon of natural nuclear reactors. Although all but the Bangombé reactor have been mined out, there is ongoing research on the geology and operation of these reactors.

For those interested in nuclear power and the management of nuclear waste, the Oklo reactors have provided an incredibly long-term nuclear-waste storage experiment. Early measurements of the migration of rare earth fission fragments found the surprising result that they had not moved far from the reactor zone into the surrounding rock over a period of the order of 1 billion years. The long-term geochemical behavior of fission products and actinides has since been studied extensively.

In drawing conclusions about geological storage and/or disposal of nuclear waste, the Oklo data are useful in two ways. Firstly, direct and detailed studies can be made on what actually happened to the fission products and actinides in these natural reactors over the last billion years or so. Secondly, the same data can be used to test and help develop sophisticated computer codes that are to be applied to new engineered waste disposal repositories and other related applications. The second step is important because conclusions drawn directly from the Oklo example may not be valid for the chemical waste form and possibly different rock types around a modern disposal site. The general conclusion, however, is that the Oklo data give confidence that radioactive waste can be safely stored in geological repositories, particularly with appropriately engineered barriers.

The Oklo reactor data have also found applications in fundamental physics. Many fundamental theories beyond the standard model of particle physics predict that the fundamental constants in the laws of nature may vary (slowly) with time. Certain isotopic production processes in a nuclear reactor depend on the value of a particular fundamental constant. Thus certain isotope ratios in the residue of the Oklo reactors can give a measure of the value of these constants a billion years ago for comparison with modern measurements.

The case most often considered is the low energy $E_r = 97.3$ meV (milli-electron volt) resonance in the neutron capture on ^{149}Sm . For this resonance the capture cross section scales as E_r^{-2} and thus it is very sensitive to any shift in the resonance energy. Measurements of $^{149}\text{Sm}/^{150}\text{Sm}$ abundance ratios in the Oklo reactors have been used to set limits on the time and spatial variations in the fine structure constant, as well as limits on variations in the quark masses (Damour and Dyson, 1996; Flambaum and Wiringa, 2009; Berengut and Flambaum, 2012; Davis et al., 2014). Such endeavors require a firm theoretical understanding of the relationship between the fundamental constant and the energy shift as well as precise isotope-ratio data.

Feasibility of fuel self-sustaining fission (“breeding”)

A typical power reactor with a ^{235}U enrichment of 3–5% clearly has more fertile ^{238}U in the fuel than fissile ^{235}U . The capture of neutrons on ^{238}U invariably leads to the production of ^{239}Pu , which is fissile. All power reactors therefore *convert* some fertile ^{238}U to fissile ^{239}Pu , and fission of this ^{239}Pu produced in the reactor core contributes to the power output of the reactor. There is the potential to increase the energy recovered from finite uranium and thorium resources by converting the fertile isotopes to fissile isotopes (Shusterman, 2021). It is even possible to *breed* more fissile material from the fertile isotope than is consumed in the fission process.

Neutron capture and decay paths for conversion and breeding

The dominant isotope in natural uranium, ^{238}U , can be converted to ^{239}Pu by neutron capture followed by two beta (β^-) decays:

In thorium-uranium conversion ^{232}Th is converted to ^{233}U by the following neutron capture and β^- decay path:

Conversion ratio and breeding ratio

The conversion ratio is defined as

$$C = \frac{\text{Fissile nuclei produced}}{\text{Fissile nuclei consumed}},$$

where the production of fissile nuclei follows the capture and decay paths indicated above, and the consumption includes both fission and capture. When the conversion ratio is larger than one, it is called the breeding ratio, sometimes designated B .

Table 1 shows the neutron production data for thermal and fast fission of the most relevant fissile isotopes for power generation. Along with the average number of neutrons produced per fission, ν , this table shows $\eta - 1$, which represents the number of neutrons available for breeding and losses following the absorption of one neutron on the pure isotope after allowing that one neutron is needed to sustain the chain reaction. We can write

$$\eta = 1 + C + \text{Capture} + \text{Loss}.$$

Table 1 Neutron production in fission. Values of ν are from ENDF/B-VII.1 (Chadwick et al., 2011). The cross sections required to evaluate the corresponding value of η are from ENDF/B-VIII.0 (Brown et al., 2018).

		^{235}U	^{239}Pu	^{233}U
Thermal neutrons (0.0253 eV)	ν	2.44	2.88	2.50
	$\eta - 1$	1.08	1.11	1.32
Fast neutrons (1 MeV)	ν	2.53	3.015	2.59
	$\eta - 1$	1.33	1.94	1.49

Note that *Capture* here is the parasitic neutron capture that does not result in the production of fissile material; capture by fertile isotopes producing fissile isotopes is included in C . Thus $\eta - 1$ is also the upper limit to the breeding ratio as it corresponds to the ideal case of no parasitic capture or loss. At thermal neutron energies neither ^{235}U nor ^{239}Pu with $\eta - 1 \approx 1.1$ are suitable fuels to drive a breeding cycle. Losses reduce the conversion ratio below one, which means that while conversion does take place, it is impossible to replace all of the fissile nuclei consumed.

Despite producing $\nu = 2.88$ neutrons per fission at thermal energies, ^{239}Pu has a low value of η because the neutron capture cross section at thermal energies is high. Breeding of ^{233}U from ^{232}Th is considered feasible at thermal energies. However, it is clear from **Table 1** that breeding is more favorable for fast-neutron induced fission in all cases of practical value. A breeding cycle based on ^{239}Pu as the fissile material and ^{238}U as the fertile material is particularly favorable.

Conversion in a thermal reactor

Returning to the case of a typical thermal power reactor, the conversion ratio can be estimated. The production of ^{239}U (and hence ^{239}Pu) can be attributed to two primary processes: (i) resonance capture of epithermal neutrons on ^{238}U , and (ii) capture of thermal neutrons on the ^{238}U . Thus, the conversion ratio can be written in terms of one minus the resonance escape probability $(1 - p)$ and in terms of η and η_{235} (the average number of neutrons produced by absorption of one neutron by pure ^{235}U). Assuming that the fast fission factor is unity, the conversion ratio in a thermal reactor can be written as

$$C = (1 - p)\eta_{235} + \left(\frac{\eta_{235}}{\eta} - 1\right),$$

where the first term is from epithermal resonant capture and the second term is from thermal capture (Bodansky, 2004). Note that the second (thermal) term is determined solely by the level of enrichment in ^{235}U , and that it increases as the enrichment decreases. The conversion ratio will therefore change with time, increasing as ^{235}U is consumed and η decreases. Graphite and heavy water moderated reactors tend to have higher conversion ratios ($C \approx 0.9$) than light water reactors ($C \approx 0.6$) because these reactors usually operate with natural or lower-enrichment uranium than light water reactors. For example, the thermal capture contribution to the conversion ratio $\left(\frac{\eta_{235}}{\eta} - 1\right)$ evaluated at 0.025 eV has the value of 0.54 for natural uranium, but is only 0.07 for 5% enriched uranium.

Because the conversion ratio depends on the uranium enrichment, it also depends on the burnup. The value of $C \approx 0.6$ corresponds to a burnup of about 60 gigawatt days per metric tonne of uranium.

Fast breeding, breeding gain and doubling time

It has been noted that breeding requires a conversion ratio in excess of 1, and that this can be achieved with fast reactors. In a fast reactor there is no moderator and cooling is usually achieved by use of a liquid metal circulating through the core. Several liquid metal fast breeder reactors have operated throughout the world. One example is the Russian-built BN-350 sodium cooled fast reactor, which was classified as a prototype with a target breeding ratio of about 1.4 (Orlov and Kochetkov, 1974). It has been reported to have achieved $C > 1.2$.

The degree of breeding achieved can be described by the *breeding gain* $G = C - 1$. It is also useful to define the doubling time, which is the length of time required to double the amount of fissile material in a breeder reactor (Murray, 2009). In other words, the doubling time is the time required to produce an excess of fissile material equal to the initial load. It can be estimated by considering a reactor with N_f fissile atoms per unit volume. The rate of fuel consumption is $N_f \sigma_a \phi$ where σ_a is the absorption cross section and ϕ is the neutron flux. From the definition of G , the rate of production of fissile atoms is

$$\frac{dN_f}{dt} = GN_f \sigma_a \phi.$$

The doubling time is then given by $T_d = \ln 2 / G \sigma_a \phi$. For $G = 0.2$, $\sigma_a \sim 1\text{b}$ and $\phi \sim 3 \times 10^{15} \text{cm}^{-2} \text{s}^{-1}$, the doubling time is over three decades. With typical doubling times of the order of decades for fast breeder reactors, it is clear that a nuclear power program based on breeding requires forward planning.

Generation IV fast reactors

Of the six Generation IV reactor types under development (Stanculescu, 2021), three are fast reactors and two are being developed with thermal and fast alternatives. In most cases the emphasis in Gen IV fast reactors is on burning actinides rather than on breeding. At present there is little economic advantage in breeding, which coupled with concerns about safeguards, has reduced the urgency for breeding. However the demonstrated possibility of breeding gives an option for almost unlimited nuclear energy in future, should it be needed.

Introduction

Nuclear reactors generate electrical power from the energy produced in nuclear fission. Fission occurs in the fuel of the reactor, which is made up of heavy elements, such as uranium, thorium, or plutonium. Upon interaction with a neutron, certain isotopes of these elements will either fission or form heavier isotopes that will subsequently fission. All elements that are capable of being used as fissionable material in fission-based reactors are part of a series of elements known as the actinides. A characteristic of each of these elements is that they are all radioactive and have no stable isotopes. Despite thorium and uranium having no stable isotopes, there are isotopes of each of them that are naturally occurring and undergo radioactive decay. In this chapter, fundamentals of the actinide elements, discovery and properties of the natural decay series for uranium and thorium, the use of these elements in nuclear fuels, and the presence of higher Z actinides in irradiated fuel will be discussed.

Actinides

The actinides are the group of elements that make up the second row of the f-block of the periodic table (Fig. 1) and span $Z = 89$ to $Z = 103$. These elements decay by alpha or beta decay or spontaneous fission. While spontaneous fission does occur and is unique to the heavier elements, alpha and beta decay are still the dominant processes within this series. Beyond their ability to fission, all isotopes of actinide elements are radioactive. Thus, fuel for a fission reactor is inherently radioactive prior to irradiation. For the purposes of this encyclopedia, actinides up through fermium will be discussed, however only those up through curium are typically present in notable quantities in nuclear reactor fuels.

Basic properties

Chemical

While actinide elements, especially uranium and plutonium, are well known because of their nuclear properties, their chemical properties are also unique. Unlike the top row of the f-block elements, the lanthanides, the actinides exhibit distinctly different behavior based on whether they are early or late period elements (Fig. 1). The break in the series is typically taken to be at or near curium. The early actinides exhibit many oxidation states in aqueous solution, similar to transition metals. The later actinides, however, often are only stable in one or two oxidation states in aqueous conditions, typically found in their trivalent form. Similarly, the lanthanides, are most often found in their trivalent state in aqueous solution with only a few of them even having accessible divalent or tetravalent forms. As a result of the transition-metal like behavior of the early actinides, the elements up through plutonium were originally assigned spots on the periodic table in the d-block. The d-block, named for its valence d-orbital electrons, is the region of the main block of the periodic table that ranges from Group 3 through Group 12. It was Glenn T. Seaborg's Actinide Hypothesis which related the similar behavior of americium and curium to the lanthanides and suggestion that the elements

starting at thorium be moved to the f-block. It is because the oxidation states of the early actinides can be manipulated readily, however, that they can be purified sufficiently to be used as reactor fuel. Lanthanides and the later actinides are challenging to separate from their neighboring elements because of their chemical similarities, which make them difficult to purify at industrial scales.

Nuclear

Alpha emission (Previtali, 2021) becomes a dominant mode of decay for elements with $Z > 83$. For actinide elements, the expected decay modes are alpha, beta, and spontaneous fission. Spontaneous fission only occurs for elements with $Z > 90$, and is a relatively minor contributor to the overall decay processes for the longer lived actinide isotopes. However, it is important to note that spontaneous fission, though minor, contributes to the overall neutron inventory of the reactor and also results in fission product formation particularly for isotopes of curium and californium with larger spontaneous fission branches. Unlike particle-induced fission processes, spontaneous fission, like alpha decay, occurs because of quantum mechanical tunneling (Krane, 2021). Even for the actinide isotopes with spontaneous fission branches that are more substantial, their spontaneous fission half-life is relatively long compared to alpha or beta decay. For ^{252}Cf , which has a 3.1% spontaneous fission branch, the spontaneous fission half life is 85.6 years compared to the alpha decay half life of 2.73 years.

Production of the actinides

Thorium and uranium both have naturally occurring isotopes which were produced prior to the formation of the earth and exist at concentrations of 12 and 2 ppm, respectively, averaged throughout the earth's crust. Naturally occurring thorium is 100% ^{232}Th with a half-life of 1.40×10^{10} years. Naturally occurring uranium, however, is a mixture of three isotopes ^{234}U , ^{235}U , and ^{238}U with abundances of 0.0054%, 0.7204%, and 99.2742%, respectively. There have been measurements of minute quantities of primordial ^{244}Pu , as well (Hoffman et al., 1971; Wallner et al., 2015). The primordial actinide isotopes are formed through the rapid neutron capture r-process which is thought to occur in the core collapse of supernovae or in neutron star-neutron star mergers. In the r-process, lower Z nuclides, undergo a series of neutron capture reactions and beta decays to produce about half of all isotopes heavier than iron (Garcia, 2021).

The naturally occurring actinide elements, thorium and uranium, were discovered decades and over a century, respectively, prior to those that are artificially produced. Uranium was discovered as a new element when Martin Heinrich Klaproth extracted it in the form of UO_2 from the uranium oxide mineral Pitchblende in 1789. It was not until 1841 when Eugène-Melchior Péligot successfully reduced UO_2 to uranium metal that it was found that Klaproth's material was in fact the oxide not the metal (Morss, 2006). Uranium was first given an atomic weight of 240 by Mendeleev in 1872, which was then measured by Zimmerman in 1882, though both of these values were overestimates based on the mass known today of 238.02891 (Meija et al., 2016). Thorium was discovered by Jöns Jacob Berzelius in 1828 when studying a thorium silicate mineral sample from Norway.

As with any other element found in geological deposits, uranium and thorium concentrations are increased in certain mineral ore bodies. Both elements tend to associate with oxygen, forming oxide and oxy-hydroxides species. There are many uranium and thorium bearing minerals, but two of the most well-known are uraninite (pitchblende) and monazite. Monazite, a rare earth phosphate mineral, is one of the most thorium-rich naturally occurring forms with Th exceeding 10^5 ppm in some samples. Thorium can replace the cerium monazite, as they can both exist as tetravalent cations and have similar ionic radii. Uraninite is composed primarily of UO_2 but has varying concentration of U_3O_8 depending on the environment in which it was formed. As a result of their decay, daughters of thorium and uranium (even pockets of gaseous radon) all the way down through lead can be found in their respective mineral deposits.

Unlike these select naturally occurring isotopes, the majority of actinides are artificially produced via nuclear reactions. The transuranic actinide elements were all discovered in a span of 21 years starting in 1940. The elements neptunium, plutonium, americium, curium, berkelium, and californium were all synthesized by the scientists at Berkeley, California, using the 60-in. cyclotron invented by Ernest Lawrence, a Berkeley physicist, or neutron irradiation at the Metallurgical Laboratory between 1940 and 1950 (Cameron, 2021). In 1940, McMillan and Abelson identified the 2.3 day activity formed in the neutron bombardment of ^{238}U as the new element 93, now known as Neptunium (Np) (McMillan and Abelson, 1940). A ^{238}U target was irradiated with neutrons at the 60-in. cyclotron and McMillan and Abelson observed that (1) the 2.3 day activity grew in from the decay of a 23 m activity, and (2) the 2.3 day activity exhibited chemistry different from known elements. At the time, element 93 was thought to be homologous (in the same periodic group) as Re, but they established that the chemistry was quite different with higher oxidation states behaving more like uranium and lower oxidation states like thorium. Seaborg, Kennedy, Mcmillan, and Wahl soon after, in 1941, reported the discovery of element 94, Plutonium (Pu). They performed several irradiations of ^{238}U with deuterons at the 60-in. cyclotron in the $^{238}\text{U}(\text{d},\text{n})^{239}\text{Pu}$ reaction, and then using the same previously established separations, isolated element 93. After awaiting the decay of the 2.3 day ^{239}Pu , alpha activity was detected. Through chemical exploration of this residual alpha emitting product, they established that it was chemically different from known alpha emitters (Seaborg et al., 1946a,b) and was presumed to be the ^{239}Pu decay daughter ^{239}Am . In the same year, Kennedy, Seaborg, Emilio Segre, and Wahl established the formation of ^{239}Pu via the reaction and decay: $^{238}\text{U}(\text{n},\gamma)^{239}\text{U} \rightarrow ^{239}\text{Pu} \rightarrow ^{239}\text{Pu}$ and also reported that ^{239}Pu undergoes neutron-induced fission (Kennedy et al., 1946). Interestingly, element 96 (Curium, Cm) was discovered in 1944, prior to element 95 (Americium, Am) in late 1944. Using the $^{239}\text{Pu}(\alpha,\text{n})^{242}\text{Cm}$ reaction, Seaborg, James, and Ghiorso, produced element 96 at the 60-in. cyclotron

(Seaborg et al., 1948a). The chemical processing and isolation, however, was performed at the Met Lab. Not long after, Seaborg, James, and Morgan produced, isolated, and characterized $^{241}\text{95}$ via reactor irradiation and subsequent separation at the Met Lab using the following sequence of reactions and decays (Seaborg et al., 1948b): $^{239}\text{Pu}(n,\gamma)^{240}\text{Pu}(n,\gamma)^{241}\text{Pu} \rightarrow ^{241}\text{95}$.

Soon after their discoveries, Am and Cm were used as target materials to explore production of heavier actinides. Due to challenges associated with previously unknown alpha decay systematics, low Am and Cm mass availability, radioactive doses from the targets, and complex trivalent actinide separations, it was not until 1950 that the discovery of element 97, Berkelium (Bk) was reported by Thompson, Ghiorso, and Seaborg. Using the Crocker Laboratory 60-in. cyclotron, Bk was produced via the reaction $^{241}\text{Am}(\alpha, 2n)^{243}\text{Bk}$ and subsequently isolated from the target material and byproduct Cm and trivalent lanthanide fission products via careful radiochemical separations (Thompson et al., 2008). With many of the production and separation challenges addressed in the Bk discovery, the isolation of element 98, californium (Cf), was reported soon after Bk in 1950 by Thompson et al. (1950). Similar to the Bk production, Cf was made in bombardment of Cm with α particles at the 60-in. cyclotron via the reaction $^{242}\text{Cm}(\alpha, xn)^{246-x}\text{Cf}$. The isotope of Cf, with a 45 min half-life was proposed to be ^{244}Cf in the original discovery paper but was later identified as ^{245}Cf .

Elements 99 and 100, einsteinium (Es) and fermium (Fm), respectively, were discovered in 1952 in the analysis of debris from Ivy Mike thermonuclear test (Ghiorso et al., 1955b). Elements 101, 102, and 103, Mendelevium (Md), nobelium (No), and lawrencium (Lr), respectively, were the first elements produced atom-at-a-time between 1955 and 1961 in charged particle reactions on targets of einsteinium, curium, and californium, respectively. For element 101, a target of ^{253}Es was bombarded with α particles at the 60-in. cyclotron at Crocker Laboratory, producing a new isotope that had chemical properties indicating that it was heavier than element 100 and decay properties expected to align with $^{256}\text{101}$ (Ghiorso et al., 1955a). There were efforts in the United States, Russia, and Sweden to produce nobelium. At the Berkeley Heavy Ion Linear Accelerator (HILAC), No was produced by bombarding Cm targets with C beams in the reaction $^{246}\text{Cm}(^{12}\text{C}, 4n)^{254}\text{102}$ (Ghiorso et al., 1958). At the 150-cm Cyclotron at the Institute of Atomic Energy in Moscow, $^{239,241}\text{Pu}$ targets were bombarded with ^{16}O to produce isotopes of No (Flerov et al., 1992). Lawrencium was produced by Ghiorso et al. also at the HILAC by irradiating a mixed isotopic Cf source with ^{10}B and ^{11}B , producing an isotope that emitted an 8.5 MeV α 's that were later attributed to ^{258}Lr (Ghiorso et al., 1961). Since that time, 15 more elements have been discovered at several laboratories around the world using a variety of reactions; these are the transactinide elements ranging from $Z = 104$ to $Z = 118$.

Fundamental processes in nuclear reactor fuels

Uranium is the most commonly used actinide element for nuclear fuel because it is the only element that has a naturally occurring fissile isotope. The nuclear reactor relies upon a careful neutron balance to sustain the nuclear chain reaction. This balance requires not only a knowledge of the number of overall neutrons, but the relative population with different energies. Fission neutrons, that is, neutrons that are emitted from a fission reaction, have a mean energy of approximately 2 MeV and an energy-dependent distribution that follows the Watt spectrum (Klay, 2021). These neutrons are considered fast because their velocity is very high. Fast neutrons have a significantly lower probability to induce fission in fissile isotopes such as ^{235}U , than thermal neutrons—neutrons that have slowed-down to thermal energies—in the vicinity of 0.025 eV at room temperature. At thermal energies, there are two dominant interaction processes that compete: neutron-induced fission and radiative capture. Both of these processes also compete with radioactive decay, which is independent of the neutron field.

Decay

Despite the early discoveries of thorium and uranium, their radioactive properties were not established for several more decades. In 1896, Henri Becquerel found that uranium-bearing materials caused blackening of photographic plates that was similar to that observed by Roentgen with X-rays. He established that this was a form of radiation. Following his methodology, in 1898, Gerhard Carl Schmidt reported that thorium-bearing materials resulted in the same effect on photographic plates and electrometers observed by Becquerel with uranium. In the same year, independent of Schmidt, Marie Skłodowska Curie measured the current generated by various compounds, including those that contained uranium and thorium, in a parallel plate condenser. Similar to Becquerel and Schmidt, she also employed photographic plates to study the activity of these materials. The two particularly notable findings from this work were that (1) thorium emitted radiation spontaneously, like uranium, and (2) uranium minerals, pitchblende and chalcocite, were more active than pure uranium indicating that a more active species than uranium was present (Curie and Lippmann, 1898). Curie's latter observation prompted her and other chemists to perform elemental separations on these minerals, from which she isolated polonium and radium.

Further investigations by Ernest Rutherford, F. Soddy, and F.E. Dorn led to the conclusion that when elements decayed via emission of radioactivity that they were converted into different elements (Rutherford and Soddy, 1902). With both chemical and radioactive properties, 40 species were isolated and then grouped into three series based on their decays. Two of these series started with uranium and one with thorium, while all terminated in stable lead. Across these series, however, there were species that had the same chemical properties but different radioactive properties. While it was not yet known what caused these differences, Soddy named these species that exhibit the same chemical properties of a given element but have different radioactive characteristics

isotopes. Once grouped by elements and isotopes, it became clear that the 40 species were actually just isotopes of the 11 elements present in the decay of ^{238}U , that make up these three decay series.

It was not until the atomic mass of uranium was measured more accurately to be closer to 238 amu that it became clear that it was the isotope ^{238}U that started the uranium series. With this information and the rule established by Fajans and Soddy that described an α -decay as $\Delta Z = -2$ and $\Delta A = -4$ while a β decay was a transition with $\Delta Z = +1$ and $\Delta A = 0$ (Soddy, 1923; Previtali, 2021) the decay series could be filled out (Fig. 2).

There are three naturally occurring decay chains: (1) uranium, (2) thorium, and (3) actinium series, each named after the naturally occurring parent element. The fourth series is the neptunium series, however, any naturally occurring ^{237}Np would have long since decayed. The mass number of all members of each of these four series can be describes as $4n + x$, where $x = 0, 1, 2$, or 3 , for the thorium, neptunium, uranium, and actinium series respectively. This classification was used to divide groups of nuclei as all mass numbers are either even divisible by 4 or have a remainder of 1, 2, or 3. The thorium series ($A = 4n$) is named for its parent ^{232}Th , the only naturally occurring isotope of thorium. This chain terminates in the formation of stable

Fig. 2 The decay chains for the uranium, actinium, and thorium series from top to bottom, respectively. Each isotope is color-coded based on their half-life ($t_{1/2}$). Each chain begins with a long-lived, naturally occurring actinide isotopes and terminates in a stable isotope of lead.

^{208}Pb . The neptunium series ($A = 4n + 1$), while not naturally occurring, is important to consider particularly for nuclear energy. The ^{237}Np parent is one of the long lived minor actinides present in used nuclear fuel, and its granddaughter, ^{233}U the fissile isotope of uranium formed in ^{232}Th breeder reactors. The original terminus in the neptunium series was ^{209}Bi , which while generally treated as stable, actually is radioactive with a half life of 1.9×10^{19} years, and so the revised end member is ^{205}Tl . The uranium series ($A = 4n + 2$) is named for its parent and the most abundant uranium isotope, ^{238}U . Between the ^{238}U and the stable ^{206}Pb endpoint, 8 α decays and 6 β decays occur. One of these intermediary isotopes is ^{226}Ra , which is why this decay chain is sometimes referred to as the radium series. Unlike the other series, the actinium series ($A = 4n + 3$) is not named after the first member of its decay chain, but rather its great-granddaughter ^{227}Ac . The parent of this series is the fissile uranium isotope, ^{235}U , and its terminus is ^{207}Pb .

Fission

In particle-induced fission processes, a heavy nucleus absorbs a particle such as a neutron or proton, and this caused the nucleus to deform into a peanut-like shape. The two lobes of the deformed nucleus maintain the positive charge of the nucleus and thus repel each other causing greater deformation. Ultimately, the repulsion leads to the splitting (fission) of the deformed nucleus to form two lighter nuclei (fission products). For fission to be energetically favorable, the binding energy of the fission products must be greater than that of the originally heavy nucleus. In this process, depending on the fissile material and incident neutron energy, 2.5 neutrons are emitted on average and the total energy release is approximately 200 MeV. This energy is split between the kinetic energy of the fission products and the neutrons, as well as prompt γ -rays emitted.

Fission is most favorable for nuclides with an even number of protons and neutrons. Spontaneous fission occurs in even-even nuclei at rates in excess of 10^3 times those of even-odd and odd-even, and 10^5 times those for odd-odd nuclei (Hyde, 1964). Similarly, neutron-induced fission with thermal neutrons is observed in nuclei with an odd number of neutrons which reach a fissionable configuration following neutron capture.

In addition to fission, another source of neutron generation in reactors is through (α , xn) reactions.¹⁴ These result from alpha particles emitted through alpha decay of the actinides interacting primarily with oxygen or fluorine nuclei in oxide or fluoride based fuels, respectively. The neutron production rate can be as high as about 4×10^6 n/s/g of actinide decaying via alpha emission. Alpha particles with higher energies result in higher neutron production rates as they are able to overcome more reaction coulomb barriers. Based on the Geiger Nutall law, alpha particle energy is inversely proportional to alpha decay half-life. Thus, as shorter-lived, higher Z actinides emit higher energy alpha particles, fuels that generate larger quantities of minor actinides can have more substantial neutron generation via this mechanism.

Capture

For heavy nuclei, the nuclear process which competes with fission and decay is neutron capture. In this process, a nucleus with mass A absorbs most often a thermal neutron and emits γ -rays (radiative capture), resulting in the formation of the isotope of the same element with a mass of $A + 1$. The radiative capture products can then go on to decay, capture neutrons, or fission. It is by this process that elements heavier than the original fuel are formed. After radiative capture, the product can β -decay, converting a neutron into a proton, and in turn forming the next element on the periodic table. The longer the fuel is in a reactor, the greater abundance of elements heavier than the fuel as well as the higher in Z that can be observed. Independent of whether the initial fuel is Th, U, or Pu, the transuranium actinides that can be produced are Np through Fm (Fig. 3). Of these actinides, Np, Pu, Am, and Cm are produced in the greatest abundance and considered during the nuclear fuel cycle. The heaviest isotope that can be produced through successful neutron capture and beta decays is ^{257}Fm (Silva, 2010). The heavier isotopes of Fm, $^{258-260}\text{Fm}$ decay nearly 100% of the time by spontaneous fission and have short half lives, with the longest lived being ^{259}Fm with a half-life of 1.5 s. Therefore, isotopes heavier than ^{257}Fm are not believed to form in a nuclear reactor.

For a given actinide isotope, the relative probability of transmutation via neutron capture or fission can be quantified via cross sections for each of these mechanisms. Once the neutron flux is considered, the competition of these modes of transmutation with radioactive decay can be determined. Both neutron capture and neutron-induced fission cross sections are dependent on the energy of the incoming neutron. The probability of a neutron interacting with a given nucleus is greater for slower neutrons, so neutron capture cross sections are highest for slow neutrons, typically of thermal energy (0.025 eV). For fissile nuclides, neutron-induced fission is the dominant form of transmutation in the presence of thermal neutrons. As evident in Table 1 their (n,f) exceed their (n, γ) cross sections by a factor of 2.5 to almost 30. The fission-to-capture ratio is generally higher for fission neutrons than for thermal neutrons. This, together with the fact that the number of neutrons emitted is larger for fast than for thermal fission, enables fast spectrum reactors to breed more fissile fuel than they consume. Each of these fissile nuclides used are long lived with the shortest half-life being that of ^{241}Pu at 14.329 years. These long half-lives ultimately mean that the decay process is not a major contributor to fissile nuclide transmutation in a reactor.

Fissionable fuels

Nuclear reactors powered by nuclear fission all rely upon fissionable fuels. A fissionable material is one that fissions upon absorption of either a slow or fast neutron. Within this set of materials, there are two subsets to consider: fissile and fertile materials. A fissile element is one that fissions only upon absorption of thermal neutron. Alternatively, fertile materials do not fission after thermal neutron absorption, but can be transmuted to fissile elements through neutron capture and subsequent beta decay.

Fissile vs. fertile fuels

^{233}U , ^{235}U , ^{239}Pu , and ^{241}Pu are all fissile isotopes, fissioning as a result of thermal neutron absorption. It is worth noting that all of these nuclei have an odd number of neutrons; those nuclei that have an even number of neutrons require higher neutron energies to fission. Of these isotopes, only ^{235}U is naturally occurring, while the other are produced from neutron capture and beta decay of fertile isotopes. The energy dependent cross sections for neutron induced fission and radiative capture are shown in Fig. 5. The higher cross sections for radiative capture compared to neutron induced fission at most energies are evident for the nuclei with an even number of neutrons, ^{232}Th and ^{238}U (Fig. 5A and D, respectively). This compares to the fissile nuclei which all have an odd number of neutrons, ^{233}U , ^{235}U , and ^{239}Pu , which have higher neutron induced fission cross sections at all energies compared to radiative capture (Figs. 5B, C, and E, respectively).

To sustain a nuclear fission chain reaction, required for power generation, the neutrons produced during fission must have at least the energy needed to induce a subsequent (n,f) reaction. This is the reason why ^{238}U alone cannot maintain a chain reaction. The average 2.5 neutrons produced in fission, prior to moderation, have a median energy of 0.7 MeV, however the threshold energy for ^{238}U fission is 1 MeV. The number of neutrons release per fission is isotope and incident neutron energy dependent (Table 1). Fissionable and fertile fuel must be enriched or designed to build up an inventory of fissile material to maintain the neutron population for a chain reaction.

All existing fuel compositions contain both fissile and fertile material. As the fissile nuclei split and release neutrons, portions of the fertile material capture those moderated fission neutrons and beta decay to produce new fissile isotopes. In uranium based fuel, for example, a fraction of the higher energy neutrons produced in ^{235}U fission can go on to fission ^{238}U . Alternatively, the ^{238}U captures the thermal neutrons to form ^{239}U which undergoes two sequential beta decays to form the fissile nuclide ^{239}Pu (Fig. 4). Now that ^{239}Pu can go on to either fission or capture a neutron to produce ^{240}Pu which has a half-life of 6561 years and will capture another neutron to form ^{241}Pu , also fissile. Ultimately, after a period of burn up, uranium based fuels can contain three of these four fissile isotopes. As ^{233}U is not naturally occurring, it is not used in the fresh fuel matrices. Rather, it is produced in a ^{232}Th -based breeder reactor. The ^{232}Th captures thermal neutrons to form ^{233}Th which forms ^{233}U through two sequential beta decays (Fig. 4), with a ^{233}Pa intermediate.

Plutonium and MA

After an irradiation cycle of between 44 and 60 GWd/ton, used nuclear fuel (UNF) is still mostly uranium ($\sim 95\%$), specifically ^{238}U (Glatz, 2021). Even after 10 years of decay after removal of the fuel from the reactor, fission products are the next most abundance species at about 4% by mass, while plutonium makes up approximately 1% and the minor actinides about 0.2% (Salvatores and Palmiotti, 2011). With a combined inventory of less than 1.5 kg/MT (MT: metric ton) fuel 10 years post end of irradiation, the minor actinides make up a relatively small mass but have notable nuclear contributions that can make them problematic. Neptunium, for instance, exists primarily in fuel at ^{237}Np which has a half life of 2.144×10^6 years, making it a long term hazard in terms of waste storage. Not as long lived are the isotopes of Am, $^{241,242,242m,243}\text{Am}$, that each have intense gamma ray emissions and contribute to long-term radiotoxicity. The major isotopes of curium that are present, namely ^{242}Cm and ^{244}Cm are both relatively short lived compared to americium and neptunium isotopes of concern. Heavier isotopes of Cm that are present in smaller quantities can impact the neutron inventory as a result of spontaneous fission.

Despite their low concentration compared to uranium and plutonium isotopes, americium and curium can have technical handling challenges as a result of their high gamma ray intensities and neutron emissions requiring shielding. In addition to producing fissile isotopes, such as ^{239}Pu and ^{241}Pu , isotopes with larger neutron capture cross sections can build up and act as a burnable poison in the fuel (Table 2). Such isotopes include ^{241}Am , ^{244}Am , and ^{238}Pu which all have cross sections on

Fig. 4 Transmutation chains for the formation of ^{233}U from ^{232}Th (left) and ^{239}Pu from ^{238}U (right).

Fig. 5 Neutron induced fission and radiative capture cross sections for (A) ^{232}Th , (B) ^{233}U , (C) ^{235}U , (D) ^{238}U , and (E) ^{239}Pu at 300 K from JENDL 4.0 (Shibata et al., 2011).

the order of 600 b. High burnup fuel can go on to form isotopes of Bk and Cf, and both ^{250}Cf and ^{251}Cf have neutron capture cross sections of greater than 1500 b. The proportion of minor actinides in UNF is a function of initial fuel matrix, neutron flux, and irradiation time. In general, thorium based UNF has lower minor actinide content than uranium or mixed oxide ($\text{UO}_2\text{-PuO}_2$ blend) fuels because more neutron captures and beta decays would be required for thorium to transmute to these elements. The exception to this is for thorium breeder reactors using minor actinides as the driver material; prior to reaching equilibrium after about 150 years, there is a greater proportion of minor actinides than would form in the fuel (Heuer et al., 2014).

Summary

Within fissionable fuels in nuclear reactors, the three primary mechanisms that transmute the actinide elements are radioactive decay, radiative capture, and fission. The fuels are blends of fissile and fertile elements, in which the proportions rely upon the type of reactor design and use. Isotopes of neptunium and transplutonium isotopes that make up the minor actinides formed in nuclear fuel can not only impact the performance of the reactor but also post-irradiation handling of the fuel and its long-term storage.

Glossary

Cross-section Measure of the effective cross-sectional area a nucleus presents to an incoming particle in order that a particular reaction is induced. Cross-section depends on the type of struck nucleus and bombarding particle, as well as the energy of the latter. Usually measured in “barns” (bn; $1 \text{ bn} = 10^{-28} \text{ m}^2$).

Critical mass Mass of a fissile material that must be gathered in one place in order to sustain a neutron-mediated chain reaction. A subcritical mass is less than this amount, and a supercritical mass is greater.

Neutron flux Measure of the number of neutrons passing through a given area per unit time within a reactor.

Pile Historical term for a nuclear reactor.

Introduction

The energy liberated by nuclear fission, about 200 Million electron-Volts (MeV) per event, is equivalent, per kilogram, to the energy released by the detonation of some 17,000 metric tons of conventional explosive. In early 1939, the verification that each fission of uranium was accompanied by the prompt release of 2–3 fast neutrons pointed to the possibility of a powerful neutron-mediated chain-reaction explosion. Within weeks of the discovery of fission, attention turned to investigating the conditions necessary for such an explosion, and understanding the physics of the fission process.

The critical mass, and the possibility of nuclear weapons

In a sample of fissile material, secondary neutrons need not cause subsequent fissions: some might be captured in non-fission reactions, and some will inevitably escape, particularly if the sample is small. As the size of the sample increases, so does the probability that a neutron will cause a fission before leaking out. A minimal critical size, and hence a corresponding critical mass of material, has to be assembled in one place in order to achieve a self-sustaining chain-reaction which will continue until the material blows itself apart.

The travel and interactions of neutrons within a reactor or bomb core can be analyzed with a simplified time-dependent diffusion theory with a single-energy group of neutrons. The first analysis of this was published by Francis Perrin in early 1939, who considered natural uranium dioxide, that is, with uranium content 0.71% of the fissile isotope ^{235}U . With very rough estimates for some of the relevant reaction cross-sections, he arrived at a critical mass of about 40,000 kg, but remarked that this could be reduced by surrounding the material with a tamper (nowadays commonly referred to as a “reflector”) to reflect escaping neutrons back into the fissile material. Perrin’s result had no relevance for a bomb, which requires essentially pure ^{235}U , but he did establish the relevant physics and introduced the notion of tampering (reflecting). Rudolf Peierls subsequently refined Perrin’s analysis to develop explicit formulae for estimating the critical mass, but did not evaluate any numbers since cross-sections were still very uncertain.

Two results of diffusion theory are key to understanding criticality.

First, for a sphere of fissile material of radius r and density ρ , criticality will be obtained so long as the product $r\rho$ exceeds a definite value, which depends on the number of neutrons emitted per fission and the fission, capture and scattering cross-sections of the material. For material of normal density, the corresponding radius and mass are usually referred to as the bare critical radius and mass; for ^{235}U and ^{239}Pu , these masses are ~ 46 and 17 kg. For a sphere of mass M , this condition is equivalent to demanding that M/r^2 exceed a definite value. This shows that a bomb containing only a single critical mass of fissile material will yield a very inefficient explosion: As soon as the chain reaction begins, the core will heat up and expand, and M/r^2 will drop below the value needed to sustain criticality. To avoid this, it is necessary to provide more than a bare-critical mass, a so-called supercritical mass. But there is a loophole: If a subcritical lump of material can be crushed to a radius less than that corresponding to its normal density before the fission chain reaction is triggered, then M/r^2 will exceed the criticality condition. This is the premise of an implosion bomb, which makes more efficient use of available fissile material.

Second, in a nuclear explosion, the fission rate in a supercritical chain reaction grows exponentially with time with an e-folding time essentially equal to the prompt neutron generation time (Klay, 2021). The prompt neutron generation time in a fast spectrum core is on the order of 10^{-8} s whereas in a thermal spectrum core, like those used for most commercial nuclear power reactors, it is several orders of magnitudes longer. For an appreciable prompt energy yield, a bomb must utilize fast neutrons; there would be no point in making a slow-neutron bomb. To utilize a fast-neutron reaction, it is necessary to isolate ^{235}U from ^{238}U ; this is discussed in the following section.

The first calculation of the energy that might be yielded by a nuclear weapon was prepared by Otto Frisch and Rudolf Peierls at the University of Birmingham, England, in March 1940, in what became known as the Frisch-Peierls Memorandum. Frisch was aware of a prediction by Niels Bohr that slow-neutron fission was likely caused by the 235 isotope of uranium, and considered whether it would be possible to make an explosive chain reaction with that isotope by using fast neutrons. With a rough guess for the fission cross-section and Peierls' critical-mass formula, Frisch estimated a mass on the order of a pound; this was low due to overestimating the fission cross-section. Taking his calculation to Peierls, they estimated that the reaction might liberate energy equivalent to thousands of tons of ordinary explosive.

Frisch and Peierls summarized their conclusions in a secret memorandum, which they showed to their department chair, Marcus Oliphant. While this was a briefing intended for government officials, it described the concept of critical mass, how such a weapon might operate, and some of the associated strategic implications with great clarity. Oliphant forwarded the document to Henry Tizard, Chairman of the British Government's Committee on the Scientific Survey of Air Warfare. Tizard asked George P. Thomson of Imperial College, London, to convene a committee to investigate the matter. Thomson served as the chair; other members included Oliphant and James Chadwick. The committee first met in April 1940, and by that summer, research was underway at various British universities on cross-sections, uranium chemistry, and isotope enrichment.

Uranium isotope effects, and the discovery of plutonium

In parallel with criticality analyses, theoretical understanding of fission was explored by Niels Bohr and John Wheeler in the first half of 1939.

The experimental evidence seemed conflicting. Both uranium and thorium could capture slow neutrons and then beta-decay to heavier elements, but tended to fission under fast-neutron bombardment. However, uranium also fissioned under slow-neutron bombardment, whereas thorium did not. Pondering how both capture and fission could proceed concurrently in uranium, Bohr and Wheeler developed an analysis which indicated that it is the rare isotope ^{235}U which is responsible for all slow-neutron fission and much of the fast-neutron fission in that element, while explaining why thorium exhibited weak fast-neutron fission but no slow-neutron fission.

Their analysis focused on the number of neutrons in nuclei. Uranium comprises two isotopes, one with an odd number of neutrons (^{235}U ; 0.7% of naturally-occurring uranium), and one with an even number (^{238}U ; 99.3%), whereas thorium has only one stable isotope, ^{232}Th , which has an even number. Since uranium exhibited slow-neutron fission while thorium did not, it appeared that the odd-neutron isotope ^{235}U might be responsible for slow-neutron fission in that element, because thorium did not possess an odd-neutron isotope. The physics behind this surmise was that, due to inter-nucleon pairing forces, even-neutron heavy-element nuclei exist in more stable mass-energy configurations than odd-neutron ones. When a nucleus captures an incoming neutron, it becomes a heavier isotope of its element with its own characteristic mass, which is always less than the sum of the masses of the original nucleus and the neutron; the lost mass appears as excitation energy of the compound nucleus in accordance with $E = mc^2$. When an odd-neutron nucleus captures an incoming neutron, the result is a higher excitation energy in the compound nucleus than when capture is by an even-neutron-number one. This indicated that when an odd-neutron nucleus such as ^{235}U captures a neutron, it could find itself in a more excited energy state and hence more prone to fission than would an even-neutron one such as ^{238}U .

Bohr and Wheeler determined that any nucleus can be induced to fission under neutron bombardment, provided that the sum of the kinetic energy of the incoming neutron and any mass-energy liberated by neutron capture exceeds a necessary activation energy, the fission barrier. For middle-weight elements, fission barriers are ~ 50 MeV, but fall to 5–6 MeV for heavy elements such as uranium, with precise values depending on the neutron number involved. Independently of this, if a nucleus undergoes an even-to-odd neutron number transition, ~ 5 MeV of binding energy are released, whereas ~ 6.5 MeV are released if the transition is odd to even.

This explained the slow/fast behavior of uranium and thorium. For ^{235}U and ^{238}U , the binding energy releases are ~ 6.5 and 4.8 MeV, respectively. However, the fission barriers for these isotopes are ~ 5.0 and 6.2 MeV. For ^{235}U , the binding energy release by itself exceeds the fission barrier; any bombarding neutron, no matter what kinetic energy it has, can induce fission in ^{235}U . But for ^{238}U , the binding-energy release falls some 1.4 MeV short of the fission barrier, which means that to fission ^{238}U requires supplying neutrons of at least this amount of energy. ^{232}Th behaves similarly to ^{238}U .

As for fast neutrons, about half the neutrons liberated in fissions have kinetic energies in excess of 1.4 MeV, so it seemed that ^{238}U could fast-neutron chain-react, but a complication intervenes. Energetic neutrons striking ^{238}U nuclei are much more likely to be inelastically scattered and lose most of their kinetic energy than they are to cause a fission; this slows them to well below the 1.4 MeV threshold. To compound this, ^{238}U has a large neutron-capture cross-section for intermediate-energy neutrons, which explained the observed capture-decay behavior of natural-abundance uranium. ^{238}U is useless as a bomb material due to this combination of scattering and capture; in a fast-neutron environment, ^{238}U is a neutron-capturing poison. By late 1939, it was becoming clear that to make a fast-neutron explosion would require isolating kilograms of the rare ^{235}U isotope from its much more abundant sister isotope.

These predictions required experimental proof, which meant isolating separate samples of ^{235}U and ^{238}U and subjecting both to neutron bombardment. The only practical method of isotope separation at the time was mass spectroscopy, and microgram-scale samples were prepared by Alfred Nier in February 1940. The ^{235}U samples showed clear evidence for slow-neutron fission, while the ^{238}U samples showed none at all. The ^{238}U samples also fissioned under fast neutrons (the threshold effect), but the ^{235}U sample was too small to test for fast-neutron fission at the time.

Despite its lack of fissility, ^{238}U did play a key role in the Manhattan Project. The ^{239}U nucleus formed in neutron capture by ^{238}U sheds energy in a series of two beta-decays, transmuting to ^{239}Pu :

^{239}Pu is an odd-neutron isotope and behaves similarly to ^{235}U in its fission properties. The great advantage of synthesizing plutonium in this way is that it obviates having to develop isotope separation technologies in order to acquire fissile material. The feasibility of actually performing this synthesis rests on the enormous fission cross-section of ^{235}U for slow neutrons. If fission-generated neutrons can be slowed with a non-neutron-capturing moderator before they are captured by ^{238}U , their probability of subsequently fissioning ^{235}U nuclei dominates over their probability of being captured by ^{238}U despite the small abundance of ^{235}U . This is what makes possible slow-neutron controlled chain-reactions utilizing natural or slightly enriched uranium, while simultaneously synthesizing ^{239}Pu .

Reaction (1) was formally proposed by Louis Turner of Princeton University in May 1940, but withheld from publication until after the war. At the time, however, the discovery of plutonium began unfolding at the University of California at Berkeley based on a speculation by Glenn Seaborg that exactly this process might occur. The first step was the isolation of ^{239}Np , which was accomplished by Edwin McMillan and Philip Abelson, also in May 1940. About a year later, a team under the direction of Glenn Seaborg isolated a fraction of a microgram of ^{239}Pu , and verified that it was fissile.

The Manhattan Engineer District: Two pathways to atomic bombs

In mid-1939, Leo Szilard and Eugene Wigner, Hungarian-born Jewish émigré physicists living in America, felt that government officials needed to be alerted to the possibility of fission as a weapon. Reasoning that Albert Einstein, a friend of Szilard, was famous enough to be recognized by anybody, they prevailed upon him to sign a letter which they intended to submit to the State Department. Another acquaintance of Szilard and an advisor to President Roosevelt, Alexander Sachs, offered instead to take the letter directly to the White House.

Sachs briefed Roosevelt on October 11, and the President ordered the Director of the National Bureau of Standards, Lyman Briggs, to assemble an advisory committee comprising himself and ordnance experts from the Army and Navy. The committee held its first meeting on October 21, hearing briefings from Szilard, Wigner, and Enrico Fermi. The War and Navy Departments contributed \$6000 to Fermi, then at Columbia University after fleeing his native Italy, so that he could purchase supplies for neutron-capture experiments being carried out with a view to establishing a chain reaction.

In June 1940, Briggs's committee was absorbed by the National Defense Research Committee (NDRC), an agency established to coordinate research which might have military applications. The NDRC was directed by Vannevar Bush, a Massachusetts Institute of Technology electrical engineer, and James Conant, a chemist and President of Harvard University. In June 1941, the NDRC would be re-named the Office of Scientific Research and Development (OSRD); by the time of Pearl Harbor, the NDRC/OSRD had let contracts totaling some \$300,000 for fission and isotope-separation research.

For independent advice on the uranium issue, Bush asked Arthur Compton to gather a committee to conduct a comprehensive review. In three reports prepared between May and November 1941, Compton's group considered reactors and bombs, concluding that fission bombs were possible. These conclusions were independently supported by George Thomson's committee in Britain, and Bush received the go-ahead from Roosevelt in late November. In March 1942, it was decided to transfer the project to the War Department in view of the anticipated costs (estimated at \$500 million) and need for secrecy. Two programs would be pursued: enriching ^{235}U , and breeding plutonium.

Fig. 1 Left: Leslie R. Groves (1896–1970). Right: Robert Oppenheimer (1904–1967), ca. 1944. Source: <http://commons.wikimedia.org/wiki/File:JROppenheimer-LosAlamos.jpg>

The Army Corps of Engineers established the Manhattan Engineer District in August 1942; its first headquarters were located in Manhattan. In September, command was assigned to Brigadier General Leslie Groves (**Fig. 1**). At the time of his appointment, Groves was responsible for overseeing all Army construction within the United States, including the Pentagon; he had intimate knowledge of contractors who could undertake complex projects.

Uranium enrichment and plutonium production reactors

The Manhattan District established two factory complexes for producing fissile materials, one at Oak Ridge, Tennessee, and one at Hanford, Washington. In addition, a highly-secret bomb-design laboratory was established at Los Alamos, New Mexico, directed by Dr. J. Robert Oppenheimer of the University of California (**Fig. 1**).

Oak Ridge was the site of three uranium enrichment facilities and a pilot-scale reactor; the location was chosen for its access to electrical power from the Tennessee Valley Authority. The three uranium-enrichment facilities, code named Y-12, K-25, and S-50, each utilized a different process. The reactor, code-named X-10, was part of the plutonium-production program, and is discussed later in this section. Oak Ridge would consume \$1.2 billion in construction and operating costs.

Y-12: Electromagnetic separation

The operating principle of the Y-12 facility was identical to that of a cyclotron, wherein an ionized atom or molecule is directed into a magnetic field in such a way that it moves in a circular trajectory whose radius depends on its mass. At Oak Ridge, these devices were called calutrons, a contraction of California University Cyclotron.

See **Fig. 2**. The large rectangle represents a vacuum tank, which contains equipment to ionize and accelerate molecules of uranium tetrachloride. The molecules are shot vertically upwards into a magnetic field, which is created by a surrounding coil and is arranged to emerge perpendicularly from the page. If the ion stream comprises molecules of two different masses, the result is two streams that travel in orbits of different radii and which can be separated. While conceptually simple, this was difficult to realize in practice: the beams had diameters of just over 3 m, and a separation of only about a centimeter.

Calutron operation is constrained by the fact that the beams repel each other and can become disrupted from their paths. At Oak Ridge, this set a limit of isolating about 0.1 g of ^{235}U per day per vacuum tank. To collect enough material for a critical mass in 1 year would require over 1000 tanks in simultaneous operation, and Y-12 eventually boasted 1152. An efficient way to arrange many tanks is to place them between magnet coils, and copy such arrangements back-to-back in a closed track connected to a source of current. The track shown in **Fig. 3** contained 96 pairs of vacuum tanks placed within 48 magnet coils, which appear as rib-like structures. The tanks could be withdrawn to extract separated material; operators monitored and adjusted the beams in each tank. The first calutrons entered operation in November 1943, and by August 1945, some 60 kg of bomb-grade uranium had been isolated.

K-25: Gaseous diffusion

To 800-m long K-25 factory at Oak Ridge housed the gaseous diffusion plant of the Project, and consumed over \$500 million in construction and operating costs (**Fig. 4**).

Gaseous diffusion is based on a result of kinetic theory. An atom in an environment at a given temperature will move in random motion with a speed that is inversely proportional to the square root of its mass. Lighter atoms move faster on average than heavier ones, and, if a gas of atoms of mixed isotopic composition is pumped against a barrier containing millions of microscopic holes, those of lower mass will pass through slightly more frequently than those of higher mass, resulting in a minute level of enrichment

Fig. 2 Schematic illustration of a calutron tank. Sketch by author from Reed BC (2019) *The History and Science of the Manhattan Project*, 2nd edn. Berlin: Springer.

Fig. 3 A Y-12 track; spare vacuum tanks appear in the lower-left corner. Source: https://commons.wikimedia.org/wiki/File:Y-12_Calutron_Alpha_racetrack.jpg

of the lighter-isotope gas on the other side of the barrier. The resulting enrichment is dictated by the ratio of the masses, so to achieve bomb-grade enrichment requires repeating the process thousands of times.

In practice, large tanks containing diffusion membranes were linked together in a cascade (Fig. 5). In the figure, feed material enters the second tank from the bottom. Gas enriched in the lighter isotope is advanced to the next stage of the cascade, while that depleted in the lighter isotope—but which still contains atoms of that isotope—is recycled for additional processing. Lighter-isotope material accumulates toward the top of the diagram, while heavier-isotope material concentrates toward the bottom. K-25 incorporated 2892 such stages, and was built between 1943 and 1945; operations began in early 1945.

S-50: Liquid diffusion

The premise of liquid diffusion is that if a gas or fluid comprising two isotopes of an element is subjected to a thermal gradient, the lighter isotope will preferentially collect toward the hotter region, while the heavier one will collect toward the cooler region. Fluid

Fig. 4 The K-25 diffusion plant. Source: https://upload.wikimedia.org/wikipedia/commons/1/1b/K25_Aerial.jpg

containing the lighter isotope will then naturally rise vertically by convection while that containing the heavier isotope falls, and the fluid slightly enriched in the lighter isotope can be drawn off for further processing.

Operationally, this employed columns of three nested pipes (Fig. 6). The inner one is heated by steam pumped through its center. The intermediate pipe surrounds the inner one, with only a quarter-millimeter separation between them, and the outer surface of the intermediate pipe is chilled by cold water pumped through the outer pipe. Liquefied uranium hexafluoride was then fed into the annulus between the two inner pipes, and material slightly enriched in ^{235}U rose to the top of the assembly, from where it was collected. The S-50 plant utilized 2142 such columns, each about 15 m high, all operating in parallel. A single column could enrich the natural-abundance feed material, 0.72% ^{235}U , to 0.86% ^{235}U . Construction began in June 1944, and all columns were in operation by March 1945.

In early 1945, Groves decided to harness the three enrichment methods in series as opposed having them compete in parallel. Ultimately, processing began by first feeding natural-abundance uranium hexafluoride to the S-50 plant. This product was then fed to the K-25 plant to be taken to 20% ^{235}U , and then to Y-12 to be enriched to 90%.

Plutonium production reactors

Enrico Fermi and his collaborators began building experimental slow-neutron piles soon after he arrived in America to take up a position at Columbia University in January 1939. Their first effort involved a cylindrical tank which held ~ 570 kg of water and into which a neutron source could be inserted. A glass bulb filled with uranium oxide was placed in the tank, and an increase in the neutron population above that when no oxide was present was detected, although criticality was nowhere near approached. Beginning about mid-1940, the group moved to constructing piles proper, columns of graphite bricks up to 8 ft. square in footprint by 11 ft. high into which could be inserted layers, cubes, or spheroids of uranium oxide or pure uranium metal. These devices were used to empirically determine optimal arrangements for the disposition of uranium within a - pile; ultimately, lumps of metal distributed in a cubical lattice pattern were deemed to be best. Column-pile work began at Columbia and was continued at the University of Chicago, to where the group relocated in early 1942 when Manhattan Project administrators decided to centralize pile work there. A total of some 30 such piles were constructed between the spring and fall of 1942; in addition, some 20 smaller piles were constructed for checking the neutron-capture properties of various batches of graphite.

By the fall of 1942, Fermi was ready to attempt a self-sustaining chain-reacting pile, CP-1. Some sources give this abbreviation as "Critical Pile 1" and others as "Chicago Pile 1." Construction began on November 16, with physicists and hired laborers assembling

Fig. 6 Sectional view of a thermal diffusion process column. From Manhattan Engineer District documents.

nearly 400 tons of graphite bricks embedded with over 19,000 spheroidal slugs of uranium metal into an ellipsoid of equatorial radius nearly four meters and polar radius just over three meters. Layers of solid graphite bricks alternated with ones containing slugs configured to form a lattice as the pile was built up. Control was effected by a system of manually and motor-driven neutron-absorbing cadmium-sheathed wooden rods that could be withdrawn from or inserted into the pile as necessary. Self-sustaining criticality was achieved on the afternoon of December 2; Fermi estimated that the pile was operating at a power of about one-half of a Watt.

With proof that a chain reaction could be created and controlled, attention turned to design of both a pilot-scale pile and full-scale plutonium production piles. The X-10 pilot pile at Oak Ridge was built to produce a few hundred grams of plutonium for research and to train operators for the full-scale piles. This was a one-megawatt, air-cooled, graphite-moderated cubically-shaped pile about 7 m on a side. A reactor fueled with natural uranium produces about three-quarters of a gram of plutonium per day per megawatt of power output; if X-10 ran for a full year at 1 MW, it would produce about 275 g of plutonium. Ultimately, it exceeded expectations.

As the pile was assembled, beveled-edged graphite bricks were laid side-by-side to form channels into which slugs of uranium could be fed through concrete shielding (Fig. 7). Irradiated slugs fell from the back of the pile into a pool of water as new ones were pushed in, and their radioactivity allowed to decay before being processed.

X-10 went critical on November 4, 1943. Expansion of the cooling system allowed operation at 4 MW, and by mid-1944, tens of grams of plutonium were being produced per month. X-10 plutonium would lead to the discovery of the spontaneous-fission crisis at Los Alamos in the summer of 1944; this is discussed in the following section.

The site chosen for plutonium production piles was a remote area in south-central Washington state near the town of Hanford on the Columbia river, from which water could be drawn to cool the piles. The site occupied over 1700 km², large enough to accommodate three well-separated 250-MW piles. They were labeled B, D, and F, corresponding to survey locations. Equally monumental would be three chemical separation plants in which irradiated fuel slugs were dissolved and their plutonium extracted.

Each pile comprised a graphite core about 12 m square by 8.5 m deep, built of some 75,000 graphite bricks. Slugs of uranium were loaded into 2004 tubes which passed through the piles, with discharged slugs falling into a pool as with X-10 (Fig. 8). Operators could remotely monitor the flow and temperature of cooling water and adjust control rods.

B-reactor achieved criticality on September 26, 1944, with about 1600 tubes loaded, and within a day was operating at 9 MW. But about an hour after reaching 9 MW, operators noticed that reactivity was declining. By the evening of the 27th, the pile had shut itself down. Surprisingly, a few hours later, it spontaneously began operating again, only to shut itself down again. From the pattern of the reactivity, it was determined that the problem was likely a fission product with a high neutron-capture cross-section. The culprit was xenon-135, which has the largest-known slow-neutron capture cross-section of any nuclide. Fortunately, it has a half-life of only about 9 h. The solution to overcoming the problem was to increase the amount of fuel in the reactor, which meant shutting down while connecting unused tubes to the cooling system. B-pile achieved its full design power of 250 MW on February 4,

1945, and D and F piles started up with full fuel loads in December 1944, and February 1945. By the spring of 1945, kilogram quantities of plutonium were making their way to Los Alamos.

Los Alamos and trinity

The mission of the Los Alamos Laboratory was to design and build combat-ready bombs incorporating the products of Oak Ridge and Hanford.

Assembling a supercritical mass of ^{235}U proved remarkably easy with what was termed the gun method (Napolitano, 2021). As sketched in Fig. 9, this utilized two sub-critical pieces of fissile material placed within the barrel of an artillery cannon. A cylindrical target piece is held fixed at the muzzle end of the barrel, while a projectile piece is fired toward the target piece from the tail end; when fully mated, the two comprise more than one critical mass. With the cannons available in World War II, some 100 microseconds elapse between when the leading edge of the projectile piece first encounters the target piece and when full assembly is achieved. This number is very important.

Fig. 10 Little Boy. Source: http://commons.wikimedia.org/wiki/File:Atombombe_Little_Boy_2.jpg

The final Little Boy uranium bomb was about 3 m long and weighed about 4400 kg, much of which was the steel tamper; the fissile material totaled to about 65 kg (**Fig. 10**). Little Boy was ready by May 1945, and enough ^{235}U for one bomb was expected to be available around August 1. Little Boy would be deployed without a full-scale test.

In the summer of 1944, Los Alamos was plunged into a crisis. Calculations indicated that once the chain reaction was initiated, only about one microsecond would be required to fission the entire bomb core. This is much less than the projectile/target assembly time, and was the origin of the problem. At some point during assembly, a critical mass will come to be present in the partially-seated core. If a stray neutron initiates the explosion before assembly is complete (that is, before the bomb reaches its highest possible level of supercriticality), the result could be a very low-efficiency predetonation. The problem emerged in April 1944, with the arrival of plutonium from Oak Ridge: the material exhibited a high rate of neutron-liberating spontaneous fissions, an unavoidable consequence of how it was produced. When an already-synthesized ^{239}Pu nucleus is struck by a slow neutron in a reactor, it has some chance of capturing the neutron and becoming ^{240}Pu as opposed to fissioning. Reactor-produced plutonium inevitably contains some ^{240}Pu , and this isotope features a spontaneous fission rate of almost half a million per second per kilogram. It became clear that during the 100-microsecond assembly time, a predetonation would be virtually guaranteed. The only option was to speed up the assembly process to on the order of a few microseconds, which would be impossible with the gun mechanism. ^{235}U does spontaneously fission, but at a rate low enough not to be a problem for the gun assembly.

The solution was implosion, where an assembly of three-dimensional explosive blocks is configured to reverse an outwardly-progressing shock wave so that it focuses inward and crushes a sub-critical core to critical density. **Fig. 11** shows a sketch of a single block in side-view cross-section; in three dimensions, imagine a five or six-sided structure about 30 cm across. Each block comprises two castings of different explosives that fit together very precisely, and which interlocks with neighboring blocks to form a spherical shell. The outer casting of each block was a fast-burning explosive, Comp B, while the inner segment was a slower-burning material, Baratol. A detonator triggers an outward-expanding detonation wave in the Comp B, which progresses to the left in the figure. When the detonation wave hits the Baratol, it too begins exploding. If the interface is of just the correct curvature, the two waves will combine to create an inwardly-directed converging wave in the Baratol.

In the Trinity and Fat Man bombs, 32 such assemblies interlocked to create a spherical shell; see **Fig. 12**. The shell surrounded an inner assembly of 32 blocks of Comp B, which was detonated by the imploding Baratol to crush the core. For combat use, the entire assembly had to be enclosed within a ballistic casing (**Fig. 13**).

Implosion was considered so novel that it was decided to use some of the Hanford plutonium in a test of the method. This was the Trinity test of July 16, 1945, conducted in southern New Mexico. The test was a spectacular success, yielding an estimated 21 kt TNT equivalent (**Fig. 14**). On August 6, the Little Boy uranium bomb was dropped at Hiroshima (~ 13 kt), and on August 9 the Fat

Man combat version of the Trinity device was dropped at Nagasaki (~21 kt). Faced with these devastating new weapons and declaration of war by Russia, the Japanese surrendered a few days later.

The German weapons program

The German nuclear program began in April 1939, when Georg Joos of the University of Göttingen wrote to the Reich Ministry of Education to alert officials to the possibilities of fission. His letter reached Abraham Esau, head of the Ministry's Reich Research Council, who arranged for a ban to be placed on exports of uranium compounds.

Esau had a research program in mind, but a rival initiative was underway. On April 24, University of Hamburg physical chemist Paul Harteck wrote to the German War Office to alert officials to the fact that fission could lead to powerful explosives. This letter reached Erich Schumann of the Ordnance Department, who passed it on to Kurt Diebner, an Army expert on nuclear physics and explosives. Esau found himself sidelined by the more powerful War Office when, in early September, he met with General Karl Becker, head of Army Ordnance, to request provision of uranium compounds. To his surprise, he was ordered to cease uranium research and told that a cache of uranium oxide he had accumulated would be confiscated.

The same week as Esau's initiative was derailed, Erich Bagge of the Leipzig Institute for Theoretical Physics (and a student of Werner Heisenberg), was ordered to report to Berlin. There he met with Diebner and Schumann, who wanted him to arrange a conference to explore the feasibility of using uranium as a source of power or explosives. Otto Hahn, who participated in the meeting, was skeptical of achieving a chain reaction, but felt that the possibility could not be entirely dismissed. A research group under Diebner was set up in Gottow (a suburb of Berlin), and Heisenberg was brought in to work out the theory of a chain reaction. At another conference 10 days later, Heisenberg reported that two routes to utilizing fission might be possible: in reactors if a suitable moderator could be found, and/or as an explosive if ^{235}U could be isolated. Harteck had already begun to conceive of a reactor wherein uranium and heavy-water moderator would be arranged in layers, and was researching isotope separation methods.

Heisenberg was to develop the theory of chain reactions, Bagge to investigate the neutron-collision properties of heavy-water, and Harteck to consider isotope separation.

At about this time, Schumann had the War Office take over the Kaiser-Wilhelm Institute of Physics (KWIP) in Berlin as a location at which to centralize the work. The director of the KWIP, Peter Debye, left for America, and Schumann replaced him with Diebner over the objections of staff and administrators, who wanted Heisenberg. Diebner's efforts to coordinate the project were constantly frustrated by scientists preferring to stay at their home institutions; Heisenberg agreed to commute from Leipzig once a week as an advisor. Personality clashes were a motif of the German program.

In a report to the War Office in February 1940, Heisenberg initiated what has become one of the enduring mysteries of the German nuclear program: whether or not he knew how to calculate the critical mass. His result, some 500 metric tons of uranium, resulted from an erroneous expression for the critical radius and apparent confusion between the roles of reactors and bombs. That he would err so dramatically is mystifying given that papers on criticality had already appeared in the open literature. In contrast, an unsigned early-1942 Army Ordnance report on a series of lectures at which Heisenberg had been one of the participants included an unattributed estimate of from 10 to 100 kg, and at a meeting with Minister of Munitions Albert Speer a few months later he allegedly claimed that a bomb about the size of a pineapple could destroy a city. But when he was interned in England with other German scientists at the end of the war and their conversations secretly recorded, Heisenberg claimed, in private conversation with Otto Hahn after learning of the bombing of Hiroshima, to have never worked out the critical mass because he never believed that it would be possible to isolate enough pure ^{235}U . One interpretation of this story is that Heisenberg did in fact know how to calculate the critical mass, but deliberately overestimated it and slowed the program as part of an effort to deny Hitler the bomb. We will never know the truth; Heisenberg himself never addressed these conflicting versions after the war, perhaps preferring to put that time behind him.

The German invasion of Belgium in May 1940, was a boon for the program. The Union Minière du Haut-Katanga mining company was headquartered in Brussels, and the firm mined rich uranium ores in the Belgian Congo, tons of which were soon on their way to Berlin. In July, planning began to house a subcritical pile on the grounds of the Kaiser-Wilhelm Institute of Biology and Virus Research, which was located next to the Physics Institute in Berlin. To deter the curious, the laboratory was designated The Virus House. The site was ready by October, and Heisenberg and others began assembling their first pile, which involved layers of uranium oxide separated by paraffin as a moderator, all held within a container suspended in water. No chain reaction was observed, and Heisenberg concluded that an ordinary-water or paraffin-moderated pile would not achieve criticality; heavy water or graphite would be necessary.

The program began to stall in early 1941. A devastating setback occurred in January, when Walther Bothe determined that graphite captured too many neutrons to serve as a moderator; his material was probably contaminated with neutron-capturing boron. This meant that the program would have to rely on heavy water as a moderator, but the only large-scale source of that commodity was an electrolysis plant in Norway. The plant produced on the order of 100 kg per year as a by-product to its main operations, but a pile would require tons. Germany began pressing for increased production, particularly after occupying Norway. Allied intelligence became aware of German interest in the plant, which was subsequently targeted with commando and bombing raids. These disrupted production to the extent that the German program never had enough moderator to achieve a chain reaction, albeit at a cost of several dozen lives. By late 1941, German forces bogged down in the battle of Moscow, and Army Ordnance decided to reduced its funding of uranium work and relinquish control back to Abraham Esau; the Army eventually withdrew from the program altogether in 1943, but Diebner's group continued its research under Esau's oversight. In mid-1942, just as the Manhattan Engineer District was being established, the program was further curtailed when Albert Speer decreed that support would be limited to construction projects, particularly a bunker to house a larger pile at the KWIP. Heisenberg garnered a personal victory in October when he was made director of the KWIP, and Diebner retreated to Gottow.

At Gottow, Diebner conceived the idea of distributing uranium as chunks within a moderator as opposed to Heisenberg's preferred schemes of layers or shells. A test pile showed no increase in neutron flux, but this idea did initiate a new direction for the German program, one similar to Fermi's approach. Eventually, the concept evolved into suspending cubes of uranium on wires directly into heavy water.

In Berlin, Heisenberg carried on with the bunker pile, although work was hampered by relentless bombing raids. The reactor vessel was a magnesium-alloy cylinder just over a meter wide, a much smaller structure than CP-1; the German program never came close to having the materials of the Allied program. Despite Diebner's superior lattice concept, time was lost in trying different plate separations to see which one gave the best neutron enhancement. Further delays occurred when it was decided in early 1945 to relocate all pile research to Haigerloch, in southern Germany, where a wine cellar carved into a cliff was enlarged to accommodate a laboratory.

The last German pile, Berlin-VIII, was located in the Haigerloch wine cellar and used Diebner's system of suspended cubes (Fig. 15). Some increase in neutron number was detected, but the pile did not achieve criticality. By April, Allied forces were closing in, and the Haigerloch group dispersed. British and American intelligence agents located the cave, seized graphite and uranium, destroyed the vessel, and blew up the cave. Many of the leaders of the German effort, including Heisenberg, were rounded up and interned in England for 6 months after the end of the war. On the evening of August 6, they were shocked to learn just how far behind their Allied counterparts they had fallen.

Summary

The Manhattan Project succeeded in developing nuclear weapons in time to affect the outcome of World War II, but thrust the world into an uncertain new era. The legacy of Manhattan lives on in the arsenals of the nuclear powers of the world, and continuing concerns with nuclear proliferation and the possibility of nuclear terrorism.

Introduction

The earliest notion regarding nuclear fusion reactions was proposed by Eddington in 1920 (Eddington, 1920). The general idea is that the light elements have an average mass per nucleon M/A which decreases with the nucleon number A until A reaches about 60. This is called the curve of binding energy, discussed earlier. One might think of the most fundamental of all possible fusion reactions to thus be the transformation of ordinary hydrogen, with a proton as its nucleus, into something with an atomic number of two. However, there is no such thing as helium-2, and it took the discovery of deuterium in 1931 by Urey (Urey et al., 1932) and the positron by Anderson in 1932 (Anderson, 1933) to work out the details of proton-proton fusion. Thus a tentative form of the reaction might be given by (Bethe, 1939):

A more subtle problem remains, however. Although this reaction conserves charge, it does not conserve nuclear spin (i.e. angular momentum). Protons and positrons both have a spin of one-half, and the deuteron has a spin of one, so that there is a discrepancy of at least one-half unit of spin. (Units here are in the reduced Planck constant $\hbar = 1.05 \times 10^{-34}$ J-s.) The missing particle in the reaction given above is a neutrino, proposed by Pauli in 1930 to explain beta decay, the decay of the neutron into a proton and electron. Adding a neutrino with a spin of $\frac{1}{2}$ allows a reaction that conserves both charge and spin:

This is the start of the nuclear reaction sequence taking place in the sun and other stars with similar mass or less mass. (More massive stars have burned out this primary fusion fuel a long time ago.) Subsequent fusion reactions have much greater reaction probabilities and proceed quickly. These reactions include:

and

Thus, this sequence of reactions converts hydrogen into helium, with the overall result that six protons will eventually be involved to form a ${}^4\text{He}$ nucleus and returning two of the protons. The total yield of this net four-proton process, including the energy created in the neutrinos and the annihilation of the positrons with the “extra” electrons generated, is 26.7 MeV.

The neutrino production is key to understanding this process. This signals that the first reaction in this sequence is governed by the “weak force” as in beta decay. The cross section for this reaction is thus remarkably low and results in a reactivity $\langle \sigma v \rangle = 1.36 \times 10^{-47} \text{ m}^3 \text{ s}^{-1}$ at the temperature of the sun’s core. Such a low reactivity explains why the sun will be around for at least another 5 billion years, and why such a massive object is required to provide the earth with enough sunlight to sustain life. Confirmation of this process comes from direct measurements of the neutrinos produced, although reconciling the total neutrinos released from the sun took an understanding of the propensity for neutrinos to oscillate between three different “flavors.” (A clear experimental picture did not emerge until the years between 1998 and 2001, and resulted in Nobel prizes for two physicists (Kajita and McDonald) in 2015.)

Subsequent nuclear reactions with alpha particles (${}^4\text{He}$ ions), ${}^3\text{He}$ ions, protons, and deuterons produce elements up to iron ($Z = 26$), representing the minimum in the curve of binding energy. To produce heavier elements, reactions with neutrons are

required. These can produce elements up to uranium ($Z = 92$). While these have not been produced to any extent in the sun, they are present in the cosmos as a result of supernovae and red giant stars.

This brings us to a discussion of fusion as an energy source on our small planet. There are a number of reactions at only slightly higher nucleon numbers which are not governed by the weak interaction but instead by the strong force. One of the more straightforward of these is the deuteron-deuteron reaction. It has two branches that occur with roughly equal probability. They are

These have reactivities $\langle \sigma v \rangle = 1 \rightarrow 100 \times 10^{-24} \text{ m}^3 \text{ s}^{-1}$ in the range of temperatures required for significant fusion reactions to take place, that is $kT = 10 \rightarrow 1000 \text{ keV}$. However, these are not the reactions that first-generation fusion reactors will employ. Instead, two other reactions are of interest:

The first reaction given, the D-T reaction, has a cross section approximately $100 \times$ that of either branch of the D-D reaction at a rather low energy (by nuclear fusion standards!) of around $80 \rightarrow 100 \text{ keV}$, and there is a similar behavior for D- ^3He . The reason for this disparate behavior between the D-D reactions and these latter reactions lies in the structure of two compound nuclei, ^5He for the D-T case and ^5Li for D- ^3He . In both cases, an excited state exists with energy just slightly above the combined rest mass of the D + T and D + ^3He nuclei, creating a resonance in the cross sections. Fig. 1 shows the situation for ^5He and D-T. A very small fraction of the D-T reactions will release a 16.8 MeV gamma, and this has been used as a diagnostic in past experiments. Fig. 2 shows the cross sections for these reactions. The resonant structure of D-T and D- ^3He is very apparent.

It is also important to consider not just the raw cross sections for these reactions, but also the reaction rate for these reactions taking place in a hot thermonuclear plasma with a distribution of plasma velocities. Thermonuclear reaction rates are given for two species 1 and 2 as

$$\text{R.R.} = \frac{n_1 n_2 \langle \sigma v \rangle}{1 + \delta_{12}},$$

with the Kronecker delta symbol being 1 if species 1 and 2 are the same and 0 if not. (This prevents counting each reaction twice when the species are the same.) The average $\langle \sigma \rangle$ is taken over the distribution of relative velocities v between two species. Often the plasma is close to Maxwellian conditions, and the distribution of relative velocities, normalized to one, is given by

$$f(v) = \left(\frac{\mu}{2\pi kT} \right)^{3/2} \exp(-\mu v^2 / (2kT))$$

Fig. 1 Energy level diagram for ^5He , showing excited state with spin $3/2^+$.

Fig. 2 Cross sections for D-T, D-³He, and D-D (both branches).

Here μ is the reduced mass $m_1 m_2 / (m_1 + m_2)$. For an isotropic distribution this can be written as a distribution in center-of-mass energies given by

$$f(E) = 2(\pi kT)^{-1/2} E^{1/2} \exp(-E/kT),$$

with E being the center-of-mass energy. Thus, for D-T fusion, most of the reactions involve particles well above the average energy $3/2 kT$. For all binary reactions, the Maxwellian-averaged reactivity $\langle \sigma v \rangle$ can be written as.

$$\langle \sigma v \rangle = \left(\frac{8}{\pi \mu kT^3} \right)^{1/2} \int_0^\infty \sigma(E) E \exp(-E/kT) dE.$$

Reactivity data is available in tabular form and as polynomial fits. See, e.g. (Bosch and Hale, 1992) for fit data for D-D, D-T, and D-³He reactions.

One might think that the ideal temperature for a fusion reactor would be the temperature for maximum reactivity, which turns out to be around $kT = 60$ keV for D-T. However, the real goal is to produce the maximum amount of fusion power per unit volume. In the case of magnetically confined plasma (explained later), the limiting factor is the amount of pressure that can be confined. This is given by

$$p = n_e T_e + n_i T_i,$$

where n_i is the total ion density and n_e is the electron density. If we assume that the electrons and ions have fully equilibrated, the electron and ion temperatures T_e and T_i are the same. Fusion plasmas are close to electrical neutrality, so that $n_e = \langle Z \rangle n_i$,

where $\langle Z \rangle$ is the average atomic number (e.g., $\langle Z \rangle = 1.5$ for a D- ^3He plasma with no impurities). Then the fusion power density (for a 50–50 mixture of two distinct ion components) is:

$$P_f = \frac{1}{4} \left(\frac{p}{1 + \langle Z \rangle} \right)^2 \frac{\langle \sigma v \rangle}{(kT)^2} E_f$$

where E_f is the reaction energy. The temperature dependence in the pressure-limited case is the term $\langle \sigma v \rangle / T^2$. The optimization of this expression generally happens at a lower temperature than the temperature for peak reactivity. For D-T, the optimum occurs at around $kT = 15$ keV; for D- ^3He the optimum is around $kT = 60$ keV and the optimum $\langle \sigma v \rangle / T^2$ for D- ^3He is about 50 times lower than the optimum in D-T. This explains why most fusion efforts are concentrated on D-T as the primary fuel for a reactor.

One should also note that inertial confinement schemes such as laser-driven or heavy ion-driven systems have no analogous pressure limit, and in general there is some time dependence in the fusion burn. The burn history has been modeled in computer codes which couple the hydrodynamics, fusion burn, and radiation loss over a complete cycle. It generally appears that a lower temperature (around 10 keV for D-T) is found to be optimum for an inertial fusion target.

Energy balance in fusion devices

The energy balance in a fusion reactor can be viewed in two different ways. One of these concerns the immediate balance of energy in the plasma, and the other is concerned with the power balance in the reactor as a complete system. Thus the plasma energy balance as well as the plant energy balance must both be considered.

First we will look at the plasma energy balance. We will consider a D-T plasma with $\langle Z \rangle = 1$ for simplicity. The conservation of energy equation then takes the form.

$$3n \frac{dT}{dt} = P_{f\alpha} + P_{inj} - P_{rad} - P_{hc},$$

with $P_{f\alpha}$ representing the portion of the fusion energy released in charged particles that is absorbed in the plasma (note that neutrons have negligible loss before exiting the plasma), P_{inj} represents the injected power from an external source such as neutral beam injection or radiofrequency heating (ohmic heating of the plasma by self-currents can also be included here), P_{rad} is the power loss from the plasma by radiation, and P_{hc} is the loss from the plasma by heat conduction. For the plasma to be in steady state, the time derivative dT/dt must be zero.

First we look at the alpha heating term $P_{f\alpha}$. The two particles ejected from a D-T fusion event are an alpha and a neutron. If we consider the D-T system to have zero momentum, Newton's law requires that the two reaction products have equal and opposite momenta. The energy released is small compared to the particle's rest masses, and therefore $E = p^2/(2m)$ for each particle. Since the alpha has a mass of (almost exactly) four times that of a neutron, the alpha carries away one-quarter of the neutrons energy, i.e. $E_\alpha = 0.2 E_f (= 3.52 \text{ MeV})$ and $E_n = 0.8 E_f (= 14.08 \text{ MeV})$. We then write $E_\alpha = E_f f_\alpha$, with $0 \leq f_\alpha \leq 0.2$, since all of the alpha energy might not be absorbed. We then can write.

$$P_{f\alpha} = \frac{n^2}{4} \langle \sigma v \rangle E_f f_\alpha.$$

Next we look at the injected power P_{inj} . We define a new quantity Q representing the ratio of the fusion power produced to the injected power: $Q = P_f/P_{inj}$. We then have the two energy gain terms as

$$P_{inj} + P_{f\alpha} = \frac{n^2}{4} \langle \sigma v \rangle E_f (f_\alpha + 1/Q)$$

Now we look at the loss terms. We will save a detailed look of the radiation loss until later and simply invent another ratio relating the radiation loss to the fusion power, $\chi_R = P_{rad}/P_f$. Plasma heat conduction is a subject of overwhelming interest in magnetic confinement fusion, but here we simply define a characteristic time τ_E for heat to leave the plasma. Since the energy content per unit volume is $3/2(n_e T_e + n_i T_i) = 3 nT$ for a $\langle Z \rangle = 1$ thermally equilibrated plasma, we have our overall energy balance.

$$P_{inj} + P_{f\alpha} - P_{rad} - P_{hc} = \frac{n^2}{4} \langle \sigma v \rangle E_f (f_\alpha + 1/Q - \chi_R) - \frac{3 n kT}{\tau_E} = 0.$$

The equation can be re-written by moving the last term to the right-hand side, dividing by n^2 and inverting, obtaining:

$$n\tau_E = \frac{3 kT}{(1/4) \langle \sigma v \rangle E_f (f_\alpha + 1/Q - \chi_R)}$$

Notice that only the product of density and energy confinement time appears in this equation and that all of the terms on the right are functions only of temperature.

We now turn our attention to the external energy balance for a fusion power plant. An energy flow diagram is shown as [Fig. 3](#). The analysis of this system was first done by J. D. Lawson in 1955 ([Lawson, 1955](#)). We envision a system where there is some

Fig. 3 Power flow diagram for a fusion power plant.

injection of energy into the fusion plasma, i.e. Q is finite. ($Q = \infty$ is referred to as “ignition”.) The energy multiplication is the primary figure of merit for the system. Lawson assumed that the thermal conversion step would consist of a conventional steam turbine and electrical generator. The efficiency of such units is governed by thermodynamics and must be less than the Carnot cycle efficiency. The maximum efficiency for a steam-based thermal converter is about $1/3$. Using this number, and assuming that the efficiency of the heating system is 1.0 , we can calculate the minimum value of Q to achieve breakeven condition, where no power is exchanged in or out of the grid. It is important to note that all of the injection power comes out as heat, along with the fusion power produced, and thus the output power is $(Q + 1)P_{inj}$. Setting the round-trip gain to one then yields

$$(Q + 1)\eta_{th} = 1,$$

which, for $\eta_{th} = 1/3$, yields $Q = 2$. (Note that $Q = 1$ often appears in the popular media as a breakeven condition, sometimes referred to as “scientific feasibility”, but $Q = 2$ is a better breakeven condition, and since the goal is to produce net power for the grid, $Q = 10$ or greater might be called “engineering feasibility”.)

We can then translate this into a required value of $n\tau_E$ for the plasma. This requires that we evaluate the radiation loss from the plasma. We look at the most optimistic case first, where only loss by bremsstrahlung is allowed. This type of radiation involves x-ray emission from the plasma caused by collisions between the electrons and ions. The x-ray photons produced have typical energies on the order of $kT_e \sim 10$ keV and are not reabsorbed by the plasma itself and not reflected by the walls of the reactor. The basic formula for bremsstrahlung power loss is

$$P_{brem} = 5.35 \times 10^{-37} n_e \sum_i n_i Z_i^2 (kT_e)^{1/2} \text{W m}^{-3},$$

with MKS units for all quantities except the electron temperature kT_e , which is given in keV. Note the sum over all ion species weighted by the square of their atomic numbers. Bremsstrahlung is increased by the presence of even small quantities of high- Z material, and furthermore, radiation from partially ionized high- Z ions (line and recombination radiation) will be present as well. But we can quantify the total radiation loss by using a simple model where all of the ions have a fictitious charge Z_{eff} . Then $n_i = n_e/Z_{eff}$ by charge neutrality and the above formula reduces to

$$P_{rad} = 5.35 \times 10^{-37} n_e^2 Z_{eff} (kT_e)^{1/2} \text{W m}^{-3},$$

and we see that Z_{eff} is really just the ratio $P(\text{dirty})/P(\text{clean})$ for the radiation found in the real, “dirty” plasma compared to the radiation expected from a pure D-T plasma with $Z = 1$ and the same electron density. Experimentally the best experience in large magnetic fusion devices finds Z_{eff} of around 2–3.

Now we can calculate the radiation parameter χ_R . A value for the reactivity is required. For D-T at $kT = 15$ keV, we have $\langle \sigma v \rangle = 2.71 \times 10^{-22} \text{m}^3 \text{s}^{-1}$. This gives a volumetric fusion power of $(n^2/4) \langle \sigma v \rangle E_f = 1.9 n_{20}^2 \text{MW m}^{-3}$. (Here n_{20} is the DT ion density in units of 10^{20}m^{-3} , a convenient quantity because a typical ion density in a magnetic confinement device is around 10^{20}m^{-3} .) Then χ_R at $kT_e = 15$ keV is $0.011 Z_{eff}$, which is to say that the radiation loss with $n_{20} = 1$ and $Z_{eff} = 2$ is around 41.4kW m^{-3} whereas the alpha heating power $= 0.2 P_f = 380 \text{kW m}^{-3}$, or about $10 \times$ larger. The energy confinement parameter is, for $Q = 2$:

$$n\tau_E = 5.85 \times 10^{19} \text{m}^{-3} \text{s}.$$

Lawson actually calculated this at a temperature $kT = 10$ keV, with a smaller reactivity, and got an easy-to-remember value for what is what we call the “Lawson criterion” for a reactor beyond breakeven:

$$n\tau_E \geq 1.0 \times 10^{20} \text{m}^{-3} \text{s}.$$

For a typical magnetic fusion device, this means a confinement time of one second.

We can carry this result over to the inertial confinement concept. “Inertial confinement” simply means that the explosive disassembly time of a compressed capsule of DT fuel is long enough to allow the Lawson criterion to be met. This time is given approximately by

$$\tau_d = \frac{R}{4c_s}.$$

Here R is the radius of the capsule and c_s is the sound speed, given by

$$c_s = \left(\frac{\gamma_e k T_e + \gamma_i k T_i}{m_i} \right)^{1/2}.$$

It is usually assumed that the adiabatic constant γ is 1.0 for electrons (isothermal) and 5/3 for the ions (adiabatic). We can write the density $n_i = \rho N_A / M_{DT}$. It is customary to use cgs units in inertial confinement applications, so Avogadro’s number $N_A = 6.02 \times 10^{23}$, and ρ is in g cm^{-3} . Putting these calculations together, we have.

$$n\tau_E \geq 5.2 \times 10^{14} \rho R \text{ cm}^{-3} \text{ s}.$$

This estimate does not include the time-dependent burn history due to compression and heating (see, e.g., [Fraleigh, 1974](#)), and a more realistic estimate drops this by a factor of roughly five, and then the equivalent Lawson criterion is

$$\rho R \geq 1 \text{ g cm}^{-2}.$$

Confinement approaches

As described above, the two basic types of confinement schemes are magnetic confinement and inertial confinement. Both of these approaches have evolved over more than 70 years of experimental and theoretical research. A historical view of the fusion program is given in ([Morse, 2018](#)).

Magnetic confinement

An early attempt at a magnetic confinement fusion device was done at the aeronautical laboratory run by NACA, the predecessor to NASA, at Langley Field near Washington, D. C. in 1938. It used a four-foot diameter aluminum torus which was covered with a copper-wire coil, which created a toroidal (in the $\hat{\phi}$ direction in cylindrical (R, ϕ, Z) geometry) magnetic field. No attempt at inducing a plasma current was done and confinement was poor. Further experimental attempts started after World War II, and most of these used some form of the “pinch effect”, where a current was passed through the plasma either along a cylindrical axis (a Z-pinch) or induced by a transformer effect in the $\hat{\phi}$ direction in a glass torus. These experiments all showed the development of instabilities causing distortion of the plasma column in the direction θ perpendicular to R and Z in the Z-pinch and perpendicular to the minor radius r and $\hat{\phi}$ in toroidal geometry, and described by a perturbation of form $\vec{\xi} \sim \exp.(im\theta)$, with $m = 1$ called a “kink” instability and $m = 0$ a “sausage” instability. These instabilities are fairly well explained by a model of the plasma assuming that it is a highly conductive fluid. This is called the ideal magnetohydrodynamic (MHD) model. The root cause of these instabilities was identified as the propensity of the plasma to seek a state of lower free energy than the symmetrical equilibrium by growing these perturbations. It was also found that adding an extra magnetic field along the $\hat{Z}$ -direction in the Z pinch or in the $\hat{\phi}$ direction stabilized these modes. [Fig. 4](#) shows the evolution of these magnetic fusion concepts.

Fig. 4 Evolution of the pinch concept. (A): Kink and sausage instabilities in z-pinch. (B) Stabilized z-pinch. (C) Tokamak schematic.

The Russian tokamak concept is illustrated in Fig. 4C. While the first tokamak was built in the early 1950s, the concept was not adopted by others until a definitive measurement of the electron temperature in the Russian tokamak T-3 was done by a British team using laser Thomson scattering in 1969, and they reported that the electron temperature kT_e was greater than 1 keV in some shots. Tokamaks have since been built in almost every country in the world engaged in fusion research, and an international project called ITER (International Thermonuclear Experimental Reactor) is underway. This € 20 billion device is expected to generate about 500 MWth of fusion power with a gain factor Q of around 10.

While the MHD stability issues are generally mitigated in the tokamak approach, some problems remain to be completely understood and solved. At places in the plasma where the magnetic field closes on itself, (called the “rational surfaces”), the ideal MHD model breaks down and finite resistivity must be considered. The plasma has a propensity to grow islands of private flux at these places, and these islands can grow and eventually overlap, causing stochastic magnetic fields and anomalously high electron heat conduction. There are some trapped particles in the machine caused by the variation of the magnetic field strength along the magnetic lines, and these trapped particles cause island growth at lower plasma pressure than otherwise. These “neoclassical tearing modes” (NTMs) can limit plasma performance. Magnetic and electrostatic turbulence can also have a negative effect on confinement. Physics at the plasma edge is also much richer and potentially deleterious than originally thought, with “edge localized modes” (ELMs) being troublesome in some instances. In general, electron heat conduction is found experimentally to be a factor of $100 \times$ to $1000 \times$ that predicted from neoclassical theory. There are, however, empirical models from fits to experimental data that suggest, using a type of “wind tunnel scaling”, that ITER is large enough to deliver its promised performance.

Inertial confinement

An alternate path to producing fusion energy was inspired by the development of thermonuclear weapons. The first successful fusion-based nuclear weapon, called Ivy Mike, was detonated in 1952. This design was based on the D-D fusion reactions. The cryogenic deuterium fuel was heated and compressed by a fission device. The so-called “H-bomb” was refined and made light enough to mount on a missile over the next decade. Weapon physicists were interested in developing a “microfusion” experiment, to test physics concepts on a laboratory scale. Recently developed laser technology was an obvious choice for the driver. (In addition, inertial fusion concepts using heavy ions as a driver have been explored.) There were also tests of small D-T capsules in the proximity of an exploding fission primary, and these experiments were named Centurion/Halite and eventually were disclosed publicly. As a result, supporters of inertial confinement approaches claim that these efforts are an interpolation in the space of fusion yield vs. driver energy, whereas magnetic fusion is an extrapolation into the unknown.

Within the inertial confinement concept, there are two main variants. Fig. 5 shows the main approaches. There are schemes where the capsule is illuminated with the beams directly, and an ablation front is generated in the capsule material. By momentum conservation, remaining capsule material and fuel is accelerated radially inward, causing compression and shock heating. Alternatively, the driver energy can be directed to the interior wall of a high-Z container with some entrance holes: a “hohlraum”. The function of the hohlraum is to convert the laser/heavy ion energy into x-rays, which then bathe the capsule containing the fuel with high-energy photons. This “indirect drive” approach has the advantage that although laser photons cannot penetrate into the capsule plasma when that plasma is dense enough to reflect them, which happens when the critical density $n_{\text{crit}} \geq m_e \epsilon_0 \omega_L^2 / e^2$ (m_e = electron mass, ω_L = laser frequency, e = electron charge, ϵ_0 = permittivity of free space), x-ray photons are at a much higher frequency and penetrate the capsule easily. A disadvantage, however, is that other pathways for energy loss can be present because of the extra conversion step.

Just as magnetic fusion has discovered technical hurdles on the way to achieving breakeven conditions, inertial fusion has encountered challenges as well. The high compression factors required (to $100 \times$ to $1000 \times$ liquid density) can cause hydrodynamic instabilities such as Rayleigh-Taylor, Kelvin-Helmholtz, and Richtmyer-Meshkov instabilities to grow and cause mixing of the fuel and ablator (Morse, 2018). The high amplitudes of the laser electromagnetic waves can cause parametric instabilities to grow,

Fig. 5 Schematics of two inertial fusion concepts. (A) Indirect drive. (B) Direct drive.

leading to conversion of the waves into backscattered energy or energy absorption in unsuitable places. These modes are stimulated Raman scattering (SRS), stimulated Brillouin scattering (SBS), and intra-beam transfer (IBT). The choice of indirect drive moves these instabilities to the hohlraum wall from the capsule interface, but does not eliminate the problem.

The largest inertial confinement fusion experiment is the National Ignition Facility (NIF) at Livermore, Ca USA. It is currently operational with 2.1 MJ of laser energy in 192 beams into an indirect-drive target. A key feature of this experiment is the conversion of the laser light from the neodymium-doped glass at a wavelength of 1.06 μm to one-third of this wavelength at 0.35 μm . The shorter wavelength mitigates the parametric instabilities to some extent. Presently the record fusion yield has only been about 3% of the laser drive energy, and much effort has been expended on capsule design, hohlraum design, laser timing and frequency spread in order to optimize performance.

Fusion technology

Fusion reactors are envisioned as advanced nuclear reactor technology and as such will share common elements with fission technology including a reactor containment structure, heat exchangers, gas or steam turbines, and electric generators. Some elements are very different from fission technology, however, and those differences are examined here.

Breeding blankets and first wall

The prime candidates for fusion fuel are D-T and D- ^3He as discussed previously. Both of these share a basic problem in that neither T nor ^3He are available in nature. But a symbiotic relationship exists between the fusion reactions and neutron-induced reactions in lithium. Lithium is present in nature in two isotopes, ^6Li and ^7Li . The neutron reactions are

The natural abundance of ^6Li is 6.7 at.%, with the balance being ^7Li . The exothermic ^6Li reaction can happen down to zero neutron energy, and the cross section is proportional to $1/v$, the neutron velocity, at lower energies. The ^7Li reaction has a threshold energy of around 2.8 MeV ($= -8/7\text{ Q}$) but has the advantage of returning a (slower) neutron. Since the D-T neutron energy is 14.08 MeV, this allows for the possibility that a mixture of the two lithium isotopes will have a tritium breeding ratio (TBR, tritium atoms made in the blanket divided by fusion neutrons produced) greater than one. It turns out that natural lithium is almost an optimum mixture, so that there is no need for enrichment or depletion of the ^6Li fraction. (Note that tritium breeding also solves the ^3He availability issue as well, because T decays to ^3He with a 12.3 y half-life.)

Different lithium formats have been proposed. Natural lithium, a liquid at blanket temperatures of around 330 $^{\circ}\text{C}$, has a high TBR but also a high electrical conductivity, which means that pumping it through a metallic structure into a magnetic field creates a situation where electromagnetic forces will require a large pumping power. Furthermore, it is reactive with air, water, and concrete. Other choices include Li_2O (a solid, perhaps gas-cooled), and FLiBe, a molten salt. These have lower TBR, but are less hazardous. Lithium-lead eutectics such as $\text{Li}_{17}\text{Pb}_{83}$ and $\text{Li}_{62}\text{Pb}_{38}$ also show high TBR as well as good energy multiplication, but have a tendency to form an oxide layer which can change their performance. Guebaly (1997) gives some details in the consideration of candidate blanket materials.

Equally important to the choice of the tritium breeding medium is the choice of first wall and structural materials. The first wall is directly exposed to fluxes of neutrons, heat, and particle exhaust from the plasma. The bulk of the particle exhaust in the form of charged particles is taken away by the magnetic field outside the burning plasma into a divertor structure, typically envisioned as an actively cooled tungsten or carbon fiber composite. The remaining hot neutral atoms and neutrons interact directly with the first wall. Since 80% of a DT fusion reaction comes out in the neutron channel, this represents the largest power component in the reactor. The 14 MeV fusion neutrons pose a threat to radiation damage on the first wall which is rather different from a fission reactor because at this higher neutron energy, more complex nuclear reactions such as (n,α) and (n,p) can take place, and these result in helium and hydrogen gas, respectively, building up in the metal matrix of the first wall. The propensity for radiation damage in materials is usually stated in "displacements per atom," or dpa; for fusion reactors, it is usually the dpa-to-helium ratio that is most important. Candidate wall and structural materials now include composites such as SiC/SiC, composite tungsten and tungsten/rhenium alloys, and reduced activation ferritic/martensitic (RAFM) and oxide dispersion strengthened (ODS) steels.

Heating systems for magnetic fusion

While creating ignited ($Q = \infty$) fusion plasma is an ultimate goal, near-term devices (including ITER) rely heavily on supplementary heating systems. While currents running through the plasma provide some ohmic (I^2R) heating, the plasma resistivity scales as $T_e^{-3/2}$ and thus becomes negligible at thermonuclear temperatures. Without some supplementary heating, there is a gap at around 2–5 keV where neither alpha heating nor ohmic heating can balance the heat loss. The two proven candidates for providing enough energy deposition to close this gap are neutral beam injection and radiofrequency (RF) heating.

Neutral beam injection (NBI) starts by making a beam of charged particles in an accelerator and then passing these ions through a gas cell which turns these energetic ions into neutrals by charge exchange. These neutrals can cross through the magnetic fields in the plasma and deposit their energy in the plasma's interior. The energy required depends on the size and particle density of the plasma: for the earlier TFTR experiment, 120 keV neutral deuterons were sufficient; for JET, 160 keV deuterons are available. But for the ITER device, beams with energies to 1.0 MeV are planned. While the former NBI systems used a relatively straightforward positive ion system, the latter will require the generation of negative H^- and D^- ions, which is done using reactive cesium metal. Issues still in question are the robustness of these high-voltage systems to electrical breakdown and thermal loads on accelerator grid structures.

RF heating systems have been used in several frequency ranges, starting with ion cyclotron resonance heating (ICRH) systems from 30 to 100 MHz, lower hybrid heating at 1–5 GHz, and electron cyclotron heating (ECH) at 90–170 GHz. ICRH systems require large antenna structures in the plasma, and the introduction of impurities into the plasma can be an issue. ECH technology is limited by the availability of high-power, high-frequency sources, and by the high power fluxes at vacuum windows into the plasma chamber.

Inertial fusion technology

A key element in taking inertial fusion to the reactor level is the development of high-efficiency (better than 10%), high repetition rate (10 Hz or higher) drivers. This can be contrasted with the large glass-based laser systems such as at the NIF facility, which have an efficiency of about one-half of 1% and can only be fired a few times a day. The current large laser systems (which produce light at 1.06 μm wavelength) also need to convert the light output to shorter wavelengths using frequency-conversion crystals, and alternative laser technologies such as KrF lasers may offer output at even shorter wavelength (0.25 μm) without needing this step. Heavy ion drivers offer some promise for high efficiency, but the experiments to date have been at a relatively small scale, and unknown beam optics and plasma-beam interactions at the target still remain as open questions.

Glossary

Chain reaction Here referring to a fission chain reaction, can be established in a system that contains sufficient amount of fissile isotopes if at least one out of 2-to-3 neutrons emitted in a fission reaction is absorbed in another fissile nucleus and causes it to fission. A super-critical chain-reaction is established if more than one neutron from a fission is causing additional fissions. In a supercritical chain reaction the fission rate grows exponentially. In a nuclear reactor the chain-reaction is controlled to maintain a constant fission rate (fixed power).

Critical mass The minimum mass of a fissile element needed to generate a sustainable chain reaction.

Enhanced radiation weapon A thermonuclear device with a low fission yield and relatively high neutron radiation yield.

Fission weapon An explosive device whose yield derives from nuclear fission. Also known as an "Atomic Bomb."

Thermonuclear weapon A device that ignites a fusion reaction with a fission reaction, followed, typically, by a fast fission reaction. Also known as a "Hydrogen Bomb."

Introduction

The energy released in an exothermic chemical reaction is measured in electron volts (eV), whereas the energy released in a nuclear reaction is measured in millions of electron volts (MeV) (Napolitano, 2021). In other words, the energy released per kilogram of "fuel" is roughly a million times larger for a nuclear reaction than for a chemical reaction.

This simple fact was obvious immediately after a revolutionary discovery in Germany in the late 1930s. In December 1938 Otto Hahn and Fritz Strassmann chemically observed intermediate mass elements created when uranium were bombarded with neutrons. Within a month, Robert Frisch and Lise Meitner correctly interpreted this observation as the yet unknown nuclear fission reaction. Europe was in the midst of large scale conflict at the time, and this would soon grow into World War II. The intersection of these circumstances led to large scale Research and Development (R&D) efforts in both Germany and the United States to produce large amounts of fissile material, with the ultimate goal of developing enormously powerful weapons based on this discovery.

The combined R&D and manufacturing effort in the US was called the Manhattan Project (Reed, 2021). At the beginning of the Manhattan Project it was already known that the isotope ^{235}U underwent fission when bombarded by low energy neutrons, and that so does the newly discovered isotope ^{239}Pu . Therefore the Manhattan Project started with two parallel efforts to accumulate and isolate large enough amounts of each of the fissile isotope.

By the end of the war, the US had successfully built and deployed "atomic bombs" based on fission. On July 16, 1945, in the Alamogordo Bombing and Gunnery Range in the New Mexico desert, the first atomic bomb was exploded. It was based on the fission of ^{239}Pu and had an estimated yield equivalent to 20,000 tons (20 kT) of TNT. On August 6 and 9, bombs based on ^{235}U and ^{239}Pu , respectively, destroyed the cities of Hiroshima and Nagasaki in Japan. More than 100,000 people were killed, and a roughly equal number were severely injured.

Soon after the War, in 1949, the Soviet Union successfully detonated a fission weapon. Both the United States and Soviet Union developed much more powerful "hydrogen bombs" based on nuclear fusion in the 1950s, and the "nuclear arms race" had begun. Both countries began to amass arsenals of "strategic nuclear weapons" that were direct threats to each others' populations.

Other countries followed with their own weapons development programs. So called "Enhanced Radiation Weapons," also known as "neutron bombs," were developed in the 1960s, capable of destroying large populations with minimal damage to buildings and structures. These were deployed as "tactical nuclear weapons" for use on the battlefield, mainly in Europe.

Nuclear weapons have today faded into the background as more modern forms of warfare have been developed and deployed. Nevertheless, sizable nuclear arsenals still exist, and their existence is cataloged and documented, and publicly available. Research continues into the development of nuclear weapons, as well as into safeguards that are meant to deter their use during hostilities between governments.

Principles of atomic bombs: Fission weapons

The explosive release of nuclear energy in a fission weapon requires a rapidly escalating series of fission events. It is natural for a nucleus undergoing fission to release several neutrons in addition to the daughter nuclear fragments, and these neutrons can in turn generate fission in the surrounding fissile nuclei. This process is known as a *chain reaction*. In order for the chain reaction to proceed rapidly enough so that an explosion results, there need to be sufficient nuclei in proximity. This sufficient amount of nuclear material is called the *critical mass*, although the density is also important. That is, it is not enough for enough fissile nuclei to be present. They must be close enough to each other so that the chain reaction is a runaway event (supercritical).

It is not difficult to design an initial neutron source which would start the chain reaction. A typical choice is a mixture of ^{210}Po and ^9Be . The isotope ^{210}Po decays 100% through α -emission to the ground state of ^{206}Pb , so no other radiations are emitted in this decay. These α particles create neutrons through the reaction $\alpha + ^9\text{Be} \rightarrow ^{12}\text{C} + \text{n}$. Interestingly, this is the same combination of isotopes with which Chadwick made the measurements which demonstrated the existence of the neutron (Chadwick, 1932).

The next step in designing a fission weapon is to identify heavy isotopes that might make a suitable nuclear fuel. In order to have a significant fission probability when bombarded by low energy neutrons, the isotope should have even Z and odd N so that the pairing energy (Napolitano, 2021) leaves the compound nucleus in a highly excited state. The isotope must have a long enough half life so that it can be accumulated by extracting it either from ore or after synthesizing it in nuclear reactions.

It was known early on that the naturally occurring isotope ^{235}U ($Z = 92$, $N = 143$) was a good candidate for the fuel of a fission weapon. It has a half life of 700 million years so a sizable primordial abundance remains today as 0.7% of natural uranium, with ^{238}U making up over 99% of the rest. Enrichment techniques were developed in the Manhattan Project which accumulated many kilograms of uranium highly enriched in ^{235}U .

Research carried out in the US at the University of California at Berkeley, in 1940 and 1941, discovered two new elements just past uranium on the periodic table. These were named neptunium (Np, $Z = 93$) and plutonium (Pu, $Z = 94$). As expected, the researchers confirmed that the isotope ^{239}Pu underwent fission when bombarded by very low energy neutrons. See Norman et al. (2015) and references therein. The half life of ^{239}Pu is only 24 thousand years, so it does not occur naturally and must be created in nuclear reactors, where neutron capture on ^{238}U creates the short lived isotope ^{239}U which beta decays to ^{239}Np which in turn beta decays to ^{239}Pu . This technology was also developed during the Manhattan Project.

When ^{239}Pu captures a neutron, it is converted into ^{240}Pu that is not fissile but has a sufficiently high probability to undergo fission spontaneously—it emits 920 spontaneous fission neutrons per second per gram. This rate of spontaneous fission is large enough to lead to an intrinsic source of neutrons in the plutonium used for nuclear weapons and complicates this weapon design.

Given the difficulty in accumulating enough fissile material, it is of course critical to know how much of a particular isotope is necessary to achieve a critical mass. However, this is not a simple calculation (Chyba and Milne, 2014). Indeed, this determination was one of the major stumbling blocks during the Manhattan Project and other international efforts. For a given geometry, one needs to determine the size scale at which neutron production through (neutron-induced) fission is counterbalanced by the loss of neutrons through the surface. It is clear that a sphere is the right shape, since this maximizes the volume-to-surface ratio, but the “critical radius” of this sphere depends on details of the neutron interaction cross sections and its propagation through the volume. The purity of the fissile material is also important, as impurities not only dilute the fuel but may also absorb neutrons. The density of the material is also important, as a higher density decreases the mean free path (mfp; the mean distance the neutron travels until it collides with the fuel nucleus) of neutrons in the fuel.

Simple estimates can be made, and sequentially improved, but modern computational techniques are needed to make accurate determinations. The critical radius for Highly Enriched Uranium (HEU that is nearly pure ^{235}U) bare sphere at nominal uranium density is 8.4 cm. For ^{239}Pu , the bare sphere critical radius is 6.3 cm (Chyba and Milne, 2014).

After the fissile material production task is accomplished, a different challenge presents itself. How does one assemble a super-critical mass from sub-critical segments so that a runaway chain reaction follows? In the Manhattan Project, different solutions were used for the uranium and plutonium devices, as shown in Fig. 1, below. Both of these approaches lead to compressing the fissile core thus increasing the fissile material density while decreasing the surface area through which neutrons can escape. The compression of the fissile material makes an initially sub-critical core to a super-critical core. The compression reduces the mfp that is inversely proportional to the fuel atomic density. In a spherical configuration, for example, a factor of 2 reduction in radius (hypothetical; just for illustrating the principle) will result in a factor of 8 increase in the fuel density implying a factor of 8 decrease in the mfp. The mfp/radius ratio will increase by a factor of 4 and the neutron leakage probability will substantially decrease enabling a super-critical chain reaction to be established. As an example: the mean path-length an average fission neutron needs to travel in ^{235}U of nominal density ($N = 4.8 \times 10^{22} \text{ cm}^{-3}$) until it induces a fission is ($\sigma_f^{-1} N^{-1} =$) 17.1 cm; that is approximately twice the radius of a bare critical sphere (the cross section for an average fission neutron to induce fission in ^{235}U is $\sigma_f = 1.22 \times 10^{-24} \text{ cm}^2$). If the sphere is uniformly compressed to a radius of 4.2 cm, the mean path-length for fission becomes 2.3 cm that is significantly smaller than the sphere radius. Of course, neutrons change direction after each collision, may lose energy (inelastic collisions) and may even be captured so that the above numerical illustration is not a realistic simulation of the neutron evolution in the system but gives a numerical illustration of the effect of compression of the fissile material on the fission probability.

For a uranium device, two sub-critical masses of ^{235}U are assembled using a “gun-type” mechanism. Conventional chemical explosives are used to drive one sub-critical mass linearly where it collides and rapidly fuses with the other sub-critical mass. This is a relatively straightforward engineering problem, and was the solution of choice.

Assembly of an Explosive Critical Mass

<https://www.atomicheritage.org/sites/default/files/styles/large/public/Fission%20Bomb%20Assembly%20Wikimedia%20Commons.jpg>

Fig. 1 The two ways to assemble for detonation a critical mass of fissile material in a fission weapon. The “Gun-type” mechanism, used for ^{235}U , fires one subcritical mass into another. The “Implosion” approach, used for ^{239}Pu , radially compresses the critical mass volume to achieve a super-critical density.

Unfortunately, this approach could not be used for a plutonium weapon. The plutonium extracted from the plutonium production reactors contains a small amount of the isotope ^{240}Pu which undergoes fission spontaneously. This required that the plutonium critical mass be assembled much more rapidly than can be achieved using a “gun-type” mechanism. A solution was devised that made use of a spherical lens of high explosives which radially compressed the plutonium core of the device. This was not as straightforward to engineer as the gun-type solution, requiring different types of chemical explosives which needed to focus their energy and to detonate synchronously around the spherical volume, but the result was nevertheless successful for both the Alamogordo test and for the Nagasaki bomb.

Principles of hydrogen bombs: Fusion weapons

It is a misnomer to refer to fission weapons as “atomic bombs,” as the explosion is due to a nuclear reaction, rather than an atomic (i.e. chemical) reaction. The term “hydrogen bomb” is more accurate, although it also has a serious misnomer with it, as much of the explosive energy from the largest of these weapons is due to fission of ^{238}U . A more accurate terminology for hydrogen bombs is “thermonuclear” devices.

The principle explosive reaction in a hydrogen bomb is the fusion of deuterium and tritium nuclei, generally called “D-T fusion” (Napolitano, 2021; Morse, 2021). In nuclear nomenclature, we write

This reaction releases about three times as much energy per unit atomic mass than does fission of ^{235}U or ^{239}Pu . There are also no limitations enforced due to critical mass, so any practical amount of fusion material can be assembled. This is one important reason that hydrogen bombs can be constructed with considerably more explosive power than fission-based weapons, typically 10 or more times the yield in the Hiroshima and Nagasaki bombs.

There is another important mechanism used to increase the yield of a hydrogen bomb. The isotope ^{238}U does not undergo fission with low energy neutrons because the neutrons and protons are all paired. However, higher energy neutrons have significant probability (here referred to as “cross-section”) for fissioning ^{238}U . The total cross section as a function of neutron energy is shown in Fig. 2, below, along with the cross sections for fission and for the release of two or three neutrons.

The ^{238}U fission cross section is effectively zero for thermal neutron energies, but rises sharply above 2 MeV, and is a large fraction of the total cross section at higher energies. Furthermore, the $(n,2n)$ and $(n,3n)$ cross sections are also large at high energies while the neutron capture cross-section at the MeV energy range is a small fraction of the fission cross section. As a result, high energy neutron interactions with ^{238}U generate more high energy neutrons, leading to a fission of one or more ^{238}U nuclei.

The additional energy needed for ^{238}U fission is found in the 14 MeV neutron released in D-T fusion. By packing in large amounts of natural uranium near the fusion fuel, again with no limitation due to critical mass constraints, the ^{238}U will undergo fission and add significantly to the explosive yield. In fact, weapons have been constructed this way which have demonstrated thousands of times the yield of the Hiroshima and Nagasaki bombs.

The successful development of thermonuclear weapons stems largely from the work of Edward Teller and Stanislaw Ulam, although the relative contribution of each is still a matter of debate. In late 1941, Enrico Fermi suggested to Teller that a fission device could be used to trigger fusion reactions. During the time he worked on the Manhattan Project, Teller devoted significant efforts toward the development of what he dubbed the “Super”—a thermonuclear weapon that could have thousands of times

Fig. 2 Fission, $(n,2n)$, $(n,3n)$ and total cross sections in barns ($1 \text{ b} = 10^{-24} \text{ cm}^2$) of ^{238}U . The reaction probability is proportional to the cross-section. Source: Japanese Evaluated Nuclear Data Library.

Fig. 3 A schematic of the fission-fusion-fission cascade style of thermonuclear weapon. A chemical explosion is detonated which implodes a fission device to achieve critical mass. Radiation from this explosion compresses the fuel column of $^6\text{Li}^2\text{H}$ and $^6\text{Li}^3\text{H}$. Fast neutrons from D-T fusion then impact the ^{238}U shell which then undergoes fission, adding enormously to the overall explosive yield. From Morland H (1979) *The H-bomb Secret*. Progressive Magazine.

the explosive power of a fission weapon. Many details of the construction of thermonuclear weapons remain highly classified. However, one of the key ideas, which may have been provided by Ulam, is apparently the physical separation of the fission trigger from the fusion fuel.

It is easiest to describe the series of events leading to the final explosion by following a specific design. Fig. 3, below, from Morland (1979), shows a schematic of a 300 kT thermonuclear weapon.

Focus first on the fusion fuel, lithium hydride that makes use of the isotope ^6Li , which is about 7% of natural lithium, and the hydrogen isotopes deuterium and tritium. The lithium binds the hydrogen isotopes into a solid form, which is not so unwieldy as gaseous hydrogen. Secondly, in the presence of neutrons, the reaction

proceeds copiously and therefore “breeds” tritium. This is particularly attractive because tritium is radioactive with a half-life of 12 years, so producing large amounts of tritium during the explosion itself makes it easier to increase the yield.

The fusion fuel is ignited by a fission explosion, triggered with an implosion device similar to that used in the plutonium bombs from the Manhattan Project. The fission explosion fills the cylindrical ^{238}U cavity with extremely intense electromagnetic radiation. This radiation comes to blackbody equilibrium on a rapid time scale, much shorter than the time scale of materials flying out from the fission explosion, owing to the fact that the speed of light is much larger than the mechanical speed of the explosion debris. The resulting radiation pressure compresses the lithium hydride fuel, raising its temperature to the point where fusion is ignited.

Fast 14 MeV neutrons from D-T fusion initiate fission in the ^{238}U shell, adding to the net explosive yield. The fission fragments are all unstable and add to the radioactive fallout from these sorts of weapons.

The first hydrogen bomb, with scale large enough so that the explosive yield was primarily due to hydrogen fusion, was detonated by the United States in November 1952. Code named "Ivy Mike", this device used cryogenic hydrogen instead of lithium hydride, and was meant to prove the principle of the staged fission-fusion-fission design. The 10 mega-ton explosion occurred on the Enewetak Atoll in the Pacific Ocean.

Enhanced radiation warheads

Soon following their development, hydrogen bombs, with their very high explosive yield, became the standard weapons in the nuclear arsenals of the United States, the Soviet Union, and other countries cultivating their nuclear capabilities. These were strategic nuclear weapons, that would be delivered by long range missiles, bombers, or submarines, to one country's soil from another.

The 1960s saw research and development of a different, so-called "tactical" nuclear weapons. These would be used on the battlefield, launched by armies attacking one another in an otherwise conventional theater of conflict. These were naturally weapons with much smaller yield, given the potential delivery range of a battlefield means of transportation. Other considerations, including the ability to maximize damage to troops, while minimizing the damage to buildings and noncombatants, figured into the designs of these weapons.

A particularly promising direction for this research was the "Enhanced Radiation Warhead," commonly called the "Neutron Bomb." This was essentially a hydrogen bomb where the first fission stage was designed with a minimal yield, and a large charge of lithium hydride was included for a large fusion yield. The ^{238}U components were removed so that the third stage that is responsible for the large yield of H-Bombs would not play a role. This meant that nearly the entire yield of neutrons from the D-T reaction would leave the explosion site.

It is this large neutron flux that is the source of the "enhanced radiation" of these weapons. With the fission blast at 10 kT or less, the blast radius could be confined to within 0.5 km, while the neutrons would deliver a dose that would cause "immediate permanent incapacitation" to troops within a radius of about 2 km. Delivery systems would be able to reach targets between 20 and 1000 km, depending on the design and deployment details. See [Kaplan \(1978\)](#).

Fig. 4 Global nuclear warhead inventories in 2019, as compiled by the Arms Control Association (ACA), an international organization that monitors worldwide nuclear stockpiles.

Fig. 5 The size of the US nuclear weapons stockpile over nearly 60 years, starting at the height of the Cold War with the Soviet Union. This is a dramatic demonstration in the power of negotiation to reduce the global nuclear threat.

The published arsenal of nuclear weapons

Nuclear weapons stockpiles by country are researched and recorded by the Arms Control Association (ACA) at <https://www.armscontrol.org/>. Fig. 4 shows a graphic from the ACA that summarizes the strategic nuclear weapon warheads in possession by all countries with nuclear arms capabilities.

Over 90% of the weapons are in the hands of the United States and Russia, and roughly one-third of these are retired and slated for dismantling. An even smaller fraction is actively deployed on ICBMs and long-distance bombers.

Thanks to the Nuclear Nonproliferation Treaty and other international efforts, the number of nuclear weapons in the world has decreased considerably since its peak in the early 1960s. Fig. 5, also from the ACA, shows the history of the US nuclear warheads stockpile over this period.

This is testimony to the success of negotiating for the common good of all parties, but it remains to remove the last of the nuclear weapons stockpiles.

Neutron energy regimes

A neutron can be freed from the atomic nucleus by various means including nuclear fission, fusion, proton spallation, and induced reactions such as ${}^9\text{Be} + \alpha \rightarrow {}^{12}\text{C} + n$ or ${}^9\text{Be} + \gamma \rightarrow {}^8\text{Be} + n$. The neutron is emitted with kinetic energy comparable to the neutron binding energy from the strong force in the nucleus, about 1–10 MeV (MeV = 10^6 electron Volts). In the case of spallation the neutron energy may be higher due to the incident proton's energy. Neutrons in this energy range are called fast neutrons. For many applications it is desirable to reduce the neutron energy; this is typically done by moderation in a low mass solid or liquid material. Neutrons that reach thermal equilibrium with a moderator are called thermal neutrons and have typical energy of 20–30 meV (meV = 10^{-3} electron Volts). Neutrons that are partially moderated are in the intermediate energy range, and epithermal if nearly thermalized.

The phenomenology of neutron interactions with matter depends very much on neutron energy. This is mainly a consequence of quantum mechanics; slow particles exhibit wave-like behavior while fast particles do not. The determining factor is the neutron's de Broglie wavelength λ , which is equal to Planck's constant divided by its momentum. (Planck's constant $h = 6.626 \times 10^{-34}$ J s = 4.136×10^{-15} eV s.) For example a fast neutron produced from a fission reaction (about 2 MeV), has $\lambda = 20$ fm (fm = 10^{-15} m), too small to be of consequence. A thermal (0.025 eV) neutron has $\lambda = 0.18$ nm (nm = 10^{-9} m), comparable to the distance between atoms in a liquid or solid, so its wave properties emerge to play an important role in its interactions. For some scientific purposes, most notably neutron scattering research, it is useful to reduce neutron energy to below the thermal regime. These are called cold neutrons (Fig. 1).

Fig. 1 Approximate neutron energy regimes showing the associated velocities and de Broglie wavelengths.

Ultracold neutrons comprise the lowest energy regime. The key feature of ultracold neutrons is that they can be trapped and stored in the laboratory. The neutron effective potential energy of a material surface, essentially a volumetric average of the strong force potential energy of its atomic nuclei, is typically about 100 neV (neV = 10^{-9} electron Volts), so a neutron with kinetic energy below that cannot penetrate the surface and must be reflected. The neutron's magnetic dipole moment is 60 neV/Tesla so neutrons that are roughly 100 neV or below can be energetically confined in a laboratory magnetic field. The mgh potential energy of a neutron in the gravitational field at the Earth's surface is 103 neV/m. Remarkably, while the origins and natural scales of the strong, electromagnetic, and gravitational forces are very different, they converge at a neutron energy of about 100 neV to enable practical trapping of neutrons using all three forces, either singly or in combination. Ultracold neutrons are produced by specialized techniques and are used to make precise scientific measurements of certain neutron properties such as its decay lifetime and hypothetical electric dipole moment.

Fast and intermediate neutron interactions

Neutrons with energy in these regimes interact as particles with atomic nuclei in matter through a variety of nuclear reactions. The probability of a reaction such as neutron capture or scattering by an atom is usually expressed as a *cross section* σ , which has units of area, usually barns where $1 \text{ b} = 10^{-24} \text{ cm}^2$. The probability P for the reaction to occur when a neutron travels a small distance δx in a material with isotopic number density N (atoms of that isotope per unit volume) is given by $P = \sigma N \delta x$.

In general, nuclear reactions are classified as *direct* when the time of interaction between the projectile, a neutron in this context, and the nucleus is comparable to the time it would take to traverse it, i.e. the nuclear diameter (a few fm) divided by the neutron velocity. Direct reactions are characterized by a weak dependence of the cross section on neutron energy and an angular distribution of final state particles that is peaked in the incident direction. There is a strong correlation between the incoming and outgoing particle momenta. Direct reactions are observed for incident neutron energies $> 10 \text{ MeV}$. Nuclear reactions are classified as *compound* when the time of interaction is much longer than the traversal time, implying a two step process. The projectile is first absorbed to form an excited compound nucleus that later decays with a characteristic lifetime and emits the final state particle(s), which are weakly correlated with the direction of the incident particle.

Cross sections for compound reactions depend strongly on energy and feature resonances (peaks) where the incident energy closely matches that of a particular state in the nuclear structure of the compound nucleus. Fig. 2 shows an example of resonance peak structure for neutron elastic scattering on ^{115}In . Nuclear resonances take the basic form of a Lorentzian distribution

$$\sigma(E) = C \frac{\Gamma^2}{(E - E_0)^2 + \Gamma^2/4}$$

where E_0 is the resonance energy and Γ is the resonance width, related to the reaction time τ by the Heisenberg uncertainty principle: $\Gamma \approx \hbar/\tau$. A short-lived compound nucleus produces a broad resonance, and a long-lived compound nucleus a narrow one. Resonance reactions are superimposed on the approximately constant scattering probability associated with the overall nuclear potential. These two phenomena may interfere quantum mechanically to produce characteristic dips in the cross section at the low energy side of each resonance. Such dips can be seen in Fig. 2.

Fig. 2 The low-energy elastic neutron scattering cross section of ^{115}In , as a function of incident energy, showing resonance peak structure. This isotope has a strong resonance at 1.44 eV (ENDF/B-VIII).

In elastic scattering a single neutron is emitted but in a different direction than the incident neutron, leaving the structure of the nucleus unchanged, and total kinetic energy is conserved. If this not the case the reaction is called inelastic. Examples of inelastic reactions are (n,n') , (n,γ) , (n,p) , and $(n,2n)$, written in standard notation where the incident particle appears before the comma and the final particle(s) after. Inelastic (n,n') reactions leave the target nucleus in an excited state. At low energy the electrostatic energy (Coulomb barrier) in medium and heavy nuclei inhibits emission of a proton into the final state so (n,p) reactions become important above about 1 MeV. The (n,p) reaction cross section for a medium nucleus, ^{56}Fe , can be seen in Fig. 3. When the excitation energy of the compound nucleus is high enough it is possible to emit multiple neutrons into the final state. This can be regarded as a statistical process. As the “temperature” of the compound nucleus increases it becomes more probable for a higher number of neutrons to boil from its surface. The excitation energy needed for this is high in medium nuclei and lower in neutron-rich heavy nuclei such as ^{238}U where neutrons are more weakly bound. These effects can be seen in Figs. 3 and 4.

In medium and heavy nuclei (atomic number $Z \geq 18$), and neutron energy < 0.5 MeV, only elastic scattering, (n,n') , and radiative capture, (n,γ) , reactions are energetically allowed. In an (n,γ) reaction, a possible reaction for most nuclei, the neutron is absorbed by the nucleus to form an isotope of the same element with an increase of one unit of atomic mass. Due to the binding energy of the strong force, a small amount of mass is lost in the process. This is converted into gamma ray energy via the Einstein relation $E = mc^2$ and one or more gamma rays totaling about 8 MeV are emitted. An (n,γ) reaction may cause the atom to become radioactive.

In light nuclei ($Z < 18$) the Coulomb barrier is small enough to allow charged particles to escape the compound nucleus with minimal excitation and therefore (n,p) or (n,α) reactions are possible at low incident energy. These reactions are very useful in

Fig. 3 Elastic (n,n) and inelastic (n,n') , (n,p) , $(n,2n)$ neutron cross sections of ^{56}Fe as a function of incident energy (ENDF/B-VIII).

Fig. 4 Elastic (n,n) and inelastic (n,n') , $(n,2n)$, $(n,3n)$ neutron cross sections of ^{238}U as a function of incident energy (ENDF/B-VIII).

Table 1 A partial list of low energy (n,p) and (n, α) reactions. Q is the energy released.

Isotope	Natural abundance (%)	Reaction	Q (MeV)	Thermal neutron absorption cross section σ_0 (barns)
He-3	0.00013	(n,p)	0.765	5333
Li-6	7.5	(n, α)	4.78	940
B-10	19.9	(n, α)	2.79	3837
N-14	99.6	(n,p)	0.624	1.86
S-33	3.1	(n, α)	3.49	115
Cl-35	75.4	(n,p)	0.615	0.489

neutron detectors, and low background neutron shielding due to the absence of penetrating secondary gamma radiation. A partial list of these is given in [Table 1](#).

Slow neutron interactions

At thermal energy and below the neutron's de Broglie wavelength is much larger than the size of a nucleus and the range of the strong nuclear force, so it is necessary to treat the incident neutron in a reaction as a quantum mechanical matter wave, not as a small particle. In this picture the nucleus is point like and the orbital angular momentum of the system is zero, greatly simplifying the physical description. A single parameter, the *neutron scattering length*, is able to account for all phenomena of the neutron-nucleus interaction. In quantum scattering theory, the scattering length is the scattering amplitude $f(k, \theta)$ in the s-wave limit and corresponds to the scattering phase shift $\delta_0 \approx -2\pi a/\lambda$, where a is the scattering length and λ is the neutron de Broglie wavelength. The scattering length has units of length, usually expressed in fm. It is a property of the neutron-nucleus system so it depends on isotope and can have a very different values for isotopes of the same element. The underlying nuclear structure physics that determine its value are complicated, and while that physics is fundamentally understood there are no reliable methods presently available to calculate neutron scattering lengths theoretically; they must be measured by experiment.

Neutron scattering lengths are complex numbers, the imaginary part accounts for neutron absorption, e.g. (n, γ), (n,p), or (n, α) reactions. They are also spin dependent. The neutron is a spin-1/2 particle ([Garcia, 2021](#)) and so has two quantum mechanical spin states: spin-up and spin-down. If the nucleus has non-zero spin, as most do, there are two possible values for the combined spin state of the neutron-nucleus system, with two corresponding neutron scattering lengths a_+ and a_- . For free atoms and gases the scattering length a includes the kinematic effect of nuclear recoil when a neutron scatters from it. In solid materials and liquids the nucleus is constrained from recoiling due to interatomic forces and the value of the scattering length is somewhat larger. In this case the *bound scattering length* b , with spin-dependent values b_+ and b_- , is used. Because they differ only by a simple kinematic recoil effect, the free and bound neutron scattering lengths a and b are not independent. They are related by the simple formula $b = a(A + 1)/A$, where A is the atom/neutron mass ratio. At thermal energy and below, resonances in the neutron-nucleus interaction are rare, notable examples include Sm-149 (2.3 meV), Cd-113 (2.8 meV), and Hf-177 (5.0 meV). Otherwise, for the vast majority of isotopes where such low energy resonances are absent, the neutron scattering length is a constant, independent of neutron energy.

Neutron scattering cross sections can be computed directly from the scattering lengths. Due to wave interference of the neutron matter wave as it scatters coherently from different nuclei in a material, two cross sections result. The *coherent* scattering cross section is given by

$$\sigma_{\text{coh}} = 4\pi \langle b \rangle^2$$

and the *incoherent* scattering cross section by

$$\sigma_{\text{inc}} = 4\pi (\langle b^2 \rangle - \langle b \rangle^2)$$

where $\langle b \rangle^2$ and $\langle b^2 \rangle$ are averages taken over the different isotopes and the spin-dependent values b_+ and b_- . (In gases the bound scattering length b is replaced by the free scattering length a in these and following equations.) The physical interpretation is that coherent scattering describes the effect of scattering centers (nuclei) in the material acting together while incoherent scattering describes the effect caused by differences in the scattering lengths. Note that $\sigma_{\text{inc}} = 0$ in the case of an isotopically pure material where the nuclear spin is zero (hence $b_+ = b_-$), for example pure C-12 or He-4. In hydrogen and hydrogenous materials such as water and polyethylene, the incoherent scattering cross section is quite large due to the strong spin dependence of the neutron-proton scattering length. Slow neutron scattering from an isolated atom is isotropic, as is neutron scattering in a gas, liquid, or amorphous solid. In materials with structural order such as crystals, neutron wave diffraction can lead to highly directional scattering, see the discussion in Neutron Optics below.

The imaginary part of the scattering length gives the probability for a slow neutron to be absorbed by the nucleus, with emission of particles from the compound nucleus such as gammas, protons, or alphas. From quantum mechanics we obtain the following result for the slow neutron absorption cross section

$$\sigma_{\text{abs}} = 2\lambda b'' - 8\pi b''^2$$

where b'' is the imaginary part of the bound neutron scattering length and λ is the neutron de Broglie wavelength. In most isotopes $b'' \ll \lambda$ for slow neutrons, the exceptions being very strong absorbers or isotopes with low energy resonances, so the second term on the right side is usually negligible. The neutron de Broglie wavelength is $\lambda = h/mv$ where mv is the neutron momentum (mass times velocity) so we find that, to excellent approximation in most materials, the neutron absorption cross section is inversely proportional to neutron velocity. This is known as the " $1/v$ " law of neutron absorption, discovered and first explained by Fermi in 1935. The physical interpretation of the $1/v$ law is important. The range of the strong nuclear force very short ($\sim \text{fm}$), and the nucleus is point like in this regime, both much smaller than the neutron de Broglie wavelength, so the probability that the neutron is absorbed is proportional to the time that its matter wave spends in contact with the nucleus, hence proportional to $1/v$. The scattering length itself is independent of neutron velocity. Only the relative velocity of the neutron and the target material is considered here; there is no contribution from the thermal motion of atoms because each neutron overlaps many of them at once and their motion averages to zero. The neutron absorption cross section has no direct dependence on target temperature. However in the case where the target and neutron moderator are in thermal equilibrium, there is an indirect temperature dependence due to the effect of moderator temperature on the neutron velocity spectrum.

The neutron, being electrically neutral, has no long range electrostatic interaction with a charged particle such as an electron, but the neutron is composed of electrically charged quarks so there is a contact interaction when its matter wave overlaps electrons in a material. This leads to the neutron-electron scattering length b_{ne} that contributes slightly to neutron scattering in a material. Its value has been measured in neutron transmission experiments to be -0.00134 fm .

Extensive tables of neutron scattering lengths and cross sections are available (Mughabghab, 2005; NCNR, 2013). Fig. 5 shows the real part of the bound scattering length $\langle b \rangle$, averaged over spin states, for stable isotopes. Tabulated thermal neutron absorption cross sections are generally given at the reference thermal neutron velocity of exactly 2200 ms^{-1} (25.3 meV). From these, the absorption cross section for other velocities or neutron velocity spectra can be computed using the $1/v$ law.

Neutron moderation and thermalization

Fast and intermediate energy neutron interactions in materials are dominated by elastic scattering collisions with atomic nuclei. In the laboratory reference frame the nucleus gains a small amount of kinetic energy due to recoil, therefore the neutron loses that same energy. Each collision results in the transfer of a fraction of the neutron's kinetic energy to the nucleus and the neutron is gradually slowed, or *moderated*, in the material. In a single collision total kinetic energy and momentum are conserved and the initial kinetic energy of the nucleus is negligible so, in close analogy to elementary classical collision theory, the fraction of neutron energy lost depends on only two quantities: the mass of the nucleus, and the neutron's deflection angle θ , i.e. the change in direction of the neutron's velocity. The minimum possible fractional energy loss is zero, when $\theta = 0$, and the maximum is $4A/(A+1)^2$, where A is the atom/neutron mass ratio, when $\theta = \pi$. Elastic scattering is isotropic and θ is effectively a random variable between 0 and π , so we have a uniform probability distribution for energy loss between zero and the maximum. It is convenient to describe the neutron energy E in terms of a logarithmic quantity called the neutron lethargy u , defined by

Fig. 5 A summary of measured real bound coherent scattering lengths $\langle b \rangle$ of stable isotopes. From Mughabghab SF (2005) *Atlas of Neutron Resonances*. Amsterdam: Elsevier.

$$u = \ln\left(\frac{10 \text{ MeV}}{E}\right),$$

and the *lethargy constant* ξ , the average logarithm of the ratio of initial to final neutron energy for a single collision which depends only on A

$$\xi = \left\langle \ln \frac{E_{\text{initial}}}{E_{\text{final}}} \right\rangle = 1 + \frac{(A-1)^2}{2A} \ln\left(\frac{A-1}{A+1}\right)$$

Fig. 6 shows a plot of the lethargy constant and consequently the average number of elastic collisions needed to moderate a neutron from initial energy 1 MeV to the bottom of the epithermal range 0.5 eV, as a function of A . In the thermal energy regime two effects emerge that greatly complicate the physics of neutron moderation: (1) the thermal kinetic energy of the nucleus may be comparable to the neutron energy so it cannot be ignored, in fact the neutron may gain energy in a collision; and (2) chemical and molecular binding energies in the material are not negligible so material dynamics may affect the collisions. In the thermal regime computer simulations are needed for quantitative studies of neutron moderation.

The distance that a neutron travels while being moderated depends on the total cross section for elastic scattering $\sigma_{\text{elas}} = \sigma_{\text{coh}} + \sigma_{\text{inc}}$ and the density of nuclei N . As may be expected from dimensional analysis, the mean free path λ between elastic collisions is given by $\lambda = 1/N \sigma_{\text{elas}}$. The path of the neutron can be regarded as a random walk between collisions, so mathematically it follows that the mean square distance $\langle R^2 \rangle$ equals the square of the step size times the number of steps. Therefore the average of the distance squared traveled by a neutron as it is moderated from initial energy E_0 to energy E is

$$\langle R^2 \rangle = n\lambda^2 = \frac{\ln(E_0/E)}{\xi N^2 \sigma_{\text{elas}}^2}$$

In neutron diffusion theory this is often quantified using the *Fermi age* parameter τ . In spite of its name, the Fermi age has units of length squared and is proportional to the mean square distance traveled in a moderator as the neutron lethargy goes from u_0 to u :

$$\tau = \frac{\lambda^2}{3\xi(1-2/3A)}(u-u_0) = \frac{1}{6}\langle R^2 \rangle$$

A population of free neutrons contained in a moderator will continue to lose energy until they reach thermal equilibrium with it, in other words until the average neutron kinetic energy closely approaches that of the atoms in the moderator so that in subsequent collisions the neutrons are as likely to gain energy as lose it. At that point the moderation process is effectively complete and the neutrons are said to be *thermalized*. Following statistical physics, the kinetic energy spectrum of thermalized neutrons is Maxwellian:

$$N(E) = N_0 \sqrt{E} e^{-\left(\frac{E}{kT}\right)}$$

Fig. 6 Lethargy constant ξ (left axis), and the average number of collisions n needed to reduce neutron kinetic energy from 1 MeV to the bottom of the epithermal range 0.5 eV (right axis), as a function of A , the ratio of atomic mass to neutron mass. Low mass materials make much more efficient neutron moderators.

Fig. 7 The Maxwellian kinetic energy spectrum of a population of neutrons thermalized in a moderator at 28 °C ($kT = 0.026$).

where $k = 1.38 \times 10^{-23} \text{ J K}^{-1}$ is the Boltzmann constant and T is the temperature of the moderator in Kelvins, see Fig. 7. The most probable energy in a population of thermalized neutrons is $\frac{1}{2}kT$ and the average energy is $\frac{3}{2}kT$. Neutron flux $\phi(E)$ is defined as the number of neutrons passing through a plane surface, per unit area per unit time, so flux equals neutron density times velocity: $\phi(E) = v\rho(E) \propto \sqrt{E}\rho(E)$. Therefore in terms of flux the Maxwellian spectrum is:

$$\phi(E) = \phi_0 E e^{-\left(\frac{E}{kT}\right)}.$$

Due to the $1/v$ law, the probability of neutron absorption in a material increases as neutrons are moderated. This is important in the design of fission reactors: fast fission neutrons are moderated by a light material such as water or graphite to enable efficient absorption by the fissile isotope in the fuel; and also for fast neutron shields such as borated water: hydrogen in the water moderates neutrons to be absorbed via the (n, α) reaction in ^{10}B . Neutron absorption in the moderator itself may be undesirable. For example research reactors are generally designed to maximize neutron flux in the core while efficient power generation is not important. Therefore research reactors often use a heavy water (D_2O) moderator to take advantage of the much smaller neutron absorption cross section of deuterium compared to hydrogen, even though it is a less efficient moderator than light water (H_2O) due to its higher mass. Cold neutrons are produced at neutron research facilities using cryogenic moderators such as liquid hydrogen or liquid deuterium.

Thermal neutron absorption cross sections and resonance integrals

Thermal neutron absorption cross sections σ_0 are tabulated at the reference thermal velocity of $v_0 = 2200 \text{ m/s}$ ($E_0 = 25.3 \text{ meV}$). To measure these precisely, a neutron source that is very well thermalized in a moderator at known temperature is used, so the neutron kinetic energy spectrum is very close to Maxwellian, and a simultaneous comparison to a well known standard cross section σ_{0s} such as $^{197}\text{Au}(n, \gamma)^{198}\text{Au}$ is made. After irradiation, the ratio of the measured sample activity A to the standard activity A_s is

$$R = \frac{A}{A_s} = \frac{\int \sigma(E)\phi(E)dE}{\int \sigma_s(E)\phi(E)dE}.$$

In the case of a purely $1/v$ absorber, $\sigma(E) = \sigma_0 \sqrt{E_0/E}$ and $\sigma_s(E) = \sigma_{0s} \sqrt{E_0/E}$ giving simply $\sigma_0 = R\sigma_{0s}$. It is usually important to correct for small departures from the $1/v$ law and departures from a pure Maxwellian neutron spectrum, in which case

$$\sigma_0 = R\sigma_s \left(\frac{g}{g_s} \right)$$

where g and g_s are the generalized g -factors calculated from the known resonance spectra and neutron transport simulations of the irradiation facility. Also of interest is the Maxwellian averaged thermal cross section σ_{macs} :

$$\sigma_{macs} = \frac{2}{\sqrt{\pi}} \frac{\int \sigma(E)\phi(E)dE}{\int \phi(E)dE} = \frac{2}{\sqrt{\pi}} \frac{\int \sigma(E)E e^{-\left(\frac{E}{kT}\right)} dE}{\int E e^{-\left(\frac{E}{kT}\right)} dE}.$$

For purely $1/v$ absorber we have $\sigma_{macs} = \sigma_0 \sqrt{E_0/kT}$.

In a nuclear reactor, the high-energy tail of the neutron energy spectrum extends well into the epithermal region where neutron capture cross sections often have complicated energy dependence due to the presence of low energy resonances. It is useful to express the epithermal neutron capture probability of a material by a *resonance integral* RI , defined as

$$RI = \int_{E_0}^{\infty} \frac{\sigma(E)}{E} dE$$

Epithermal neutrons in a reactor usually have a $1/E$ spectrum so this applied as a weight factor inside the integral. By convention a low energy cutoff $E_0 = 0.5$ eV is used, applied in practice by using a cadmium filter. Important corrections include a high-energy weighting function to account for the typically rapid decrease in flux above 1 MeV, and the self-shielding factor that accounts for dips in the neutron flux spectrum caused by strong resonances in the sample. Resonance integrals are measured experimentally and are tabulated for many isotopes and materials.

Free neutron decay

The free neutron is not a stable particle, it decays into a proton, electron, and antineutrino with a mean decay lifetime of 880 s. This weak nuclear decay is possible because the neutron mass exceeds the total mass of the final state particles, so energy is released via the Einstein relation $E = \Delta mc^2$. Neutron decay is the most basic example of nuclear beta decay. It has important consequences in astrophysics, cosmology, and particle physics. The loss of neutrons due to free decay in a moderator or reactor is insignificant because the decay lifetime is much longer than the typical neutron capture lifetime in a material.

Neutron optics and scattering science

When a neutron's de Broglie wavelength exceeds the interatomic spacing in a material, as is the case for thermal energy and below, it may interact coherently with many nuclei at once. Each point-like nucleus acts as a scattering site for the neutron wave and produces a secondary spherical wave according to Huygen's principle. These scattered waves, all associated with a single neutron according to quantum mechanics, interfere with the incident wave and each other to produce optical phenomena such as diffraction and refraction that are closely analogous to those of light waves in a transparent medium.

In a crystal, the neutron wave scatters simultaneously from many lattice points to produce constructive interference (diffraction) when Bragg's Law, $n\lambda = 2d \sin \theta$, is satisfied for some set of lattice planes in the crystal. Here d is the spacing of lattice planes, θ is the neutron incident angle, λ is the neutron wavelength, and n is the diffraction order. Bragg's law is a geometric consequence of wave scattering in a crystal so it is essentially no different for neutrons and x rays. Neutron diffraction has a number of advantages over x rays in solid state physics and materials science research: (1) neutrons are much more penetrating and can illuminate a much larger sample volume; (2) in the relevant wavelength range, neutron kinetic energy is comparable to chemical and molecular binding energies in a material, so material dynamics can be effectively investigated; and (3) the neutron's magnetic dipole moment contributes to the spin-dependence of the scattering length, so magnetic phenomena such as ferromagnetism and superconductivity can be studied. The relative disadvantage of neutron diffraction is that the beam intensities at the best neutron sources are far lower than at a synchrotron x ray source so measurements are much slower. Fig. 8 shows an example of a crystal neutron diffraction pattern.

When a neutron enters a material it feels an effective potential energy, a volumetric average of the strong force potentials of the individual nuclei, that is proportional to the average scattering length $\langle b \rangle$ and density of nuclei N :

$$V_{\text{eff}} = \frac{h^2}{2\pi m} N \langle b \rangle.$$

In most materials V_{eff} is positive and on the order of 100 neV. When a neutron enters the material, it slows and its wavelength increases, causing refraction. This can be expressed as an index of refraction n , similar to that of light:

$$n = 1 - \frac{N \langle b \rangle \lambda^2}{2\pi}.$$

The neutron index of refraction in vacuum is 1, and it is slightly less than 1 in a medium, rather than larger as with light. This is because the neutron wave is nonrelativistic, its velocity is inversely proportional to wavelength, not proportional as for a light wave. The dependence of n on λ^2 shows that neutron refraction is dispersive. Refraction of neutron waves has been exploited in devices that manipulate slow neutron beams, such as neutron guides (analogous to fiber optics), neutron lenses, and neutron prisms.

In the last few decades neutron imaging has developed into a very useful tool for a broad range of scientific researchers. In a traditional x ray radiograph, contrast is obtained from differences in electron density within an object. High density materials such as calcium in bones absorb x rays much more strongly than low density materials such as skin and muscle. In a neutron radiograph, neutrons are removed from a beam by scattering from materials with high scattering length density. Neutrons scatter from nuclei, not electrons, and neutron scattering lengths have no significant dependence on atomic number, as seen in Fig. 5. In particular

Fig. 8 A Laue photograph of neutron Bragg diffraction from a $\text{Cu}_2\text{ZnSnS}_4$ crystal (Iles and Schoor, 2016). Dark spots are caused by different Bragg reflections.

hydrogen has a large incoherent scattering length $b_{\text{inc}} = \sqrt{\langle b^2 \rangle - \langle b \rangle^2}$ while the scattering length densities in metals such as nickel and lead are relatively low, so neutron radiographs excel at something x ray radiographs cannot do: imaging hydrogenous materials imbedded within metal or stone. A beautiful example can be seen in Fig. 9. Because neutrons are much more penetrating than x rays, neutron radiography has been used to nondestructively image small features and defects within large dense objects such turbine blades, geological samples, and archeological objects. Neutron tomography, where multiple images are taken as a sample is rotated, can be used to construct virtual 3D neutron images of the interior of an object, similar to an x ray CAT scan.

Important centers for neutron scattering and optics research include the Spallation Neutron Source (Oak Ridge, Tennessee, USA), the Institute Laue-Langevin (Grenoble, France), the NIST Center for Neutron Research (Gaithersburg, Maryland, USA), and the European Spallation Source (under construction in Lund, Sweden).

Neutron cross sections and related data online

A number of online databases provide tabulated lists and plotting tools for neutron reaction data such as cross sections, resonance integrals, and scattering lengths. They are searchable by target element, isotope, reaction, and energy. These include the international Evaluated Nuclear Data File (ENDF), the Japanese Evaluated Nuclear Data Library (JENDL), and NuDat2.

Introduction

Photons and charged particles are produced in naturally-occurring decays of radioactive isotopes and in nuclear reactions. They are produced in the cosmos and on Earth, via both naturally-occurring and man-made processes. In the cosmos, they fuel stars as protons fuse to form helium and go on to produce small amounts of heavier elements such as lithium, beryllium, boron, carbon, nitrogen, and oxygen in smaller stars, and in heavier stars, all the way up to iron. Elements heavier than iron are produced through two distinct neutron capture mechanisms known as the s-(slow) and r-(rapid) processes. Here on Earth, naturally occurring radioisotopes such as ^{238}U and ^{232}Th produce photons in the form of gamma rays and X-rays, neutrons, and charged particles such as alpha particles as they decay. We also produce photons and charged particles in particle accelerators and in nuclear reactors.

Knowing how photons and charged particles interact with matter is critical as we maintain and improve the safety and efficiency of current technology for nuclear energy generation, radiation detection, medical imaging, and radiation therapy.

Photons and charged particles will keep moving unaltered with the same energy and momentum in vacuum. When they encounter matter, photons and charged particles interact with the electrons and nuclei of the atoms of the matter and may be deflected, lose energy, or stopped. The amount of deflection and energy loss depend on the type of the incoming particle and what materials they encounter. Charged particles emitted at energies of MeV's from radioactive decay or nuclear reactions would typically travel less than 100 μm . Electrons such as those emitted in β decays may travel 0.1 to several mm in solids, while for MeV γ rays the range can be 5 cm or longer. The amount of energy lost per each encounter as well as the density of the material will determine how far the incoming photons and charged particles will travel.

Electrons and heavier charged particles such as protons and alpha particles interact through the coulomb force with the electrons in the materials they pass through. Uncharged radiations such as neutrons, X-rays and gamma-rays are not subject to coulomb force. They can either pass through matter without any interactions if thin enough or undergo a more catastrophic interaction that radically alters the properties of the incident radiation in a single encounter. These interactions result in the full or partial transfer of energy of the incident neutrons or photons to the electrons or nuclei of the atoms of the materials through which they pass.

Photons interact primarily with the orbital electrons and depending on their energy, can undergo pair production, Compton scattering, or photoelectric effect. In contrast, charged particles such as electrons, muons, alpha particles, and other ionized atoms interact with and impart energy to the orbital electrons and the nucleus. Through these individual interactions, charged particles may change their directions, excite or liberate electrons from their atomic orbits, excite nuclei, or induce nuclear interactions. High energy photons can also induce nuclear reactions, such as photofission.

In this article we discuss how photons interact with matter and how charged particles such as electrons, protons, and other ions interact with matter. We limit our discussion to radiations that we are likely to encounter in nuclear decay and nuclear energy production: photons in the X-ray and γ -ray regions, electrons and positrons up to MeV energies, and heavy charged particles (protons, α 's, and ions). Neutron interactions are considered separately in Chapter 1.9, *Phenomenology of Neutron Interactions*.

Interaction of photons with matter

Of the many interaction mechanisms possible, there are three primary ways X-ray and γ -ray photons interact with matter at relevant nuclear energies: photoelectric effect, Compton scattering, and pair production.

In the photoelectric effect, the photon is absorbed by an atomic electron and the electron is ejected from the atom. In Compton scattering, a photon scatters from an atomic electron. In pair production, a photon is converted to an electron-positron pair. When a photon is traveling through a medium, one can describe the interactions of photons with matter as a sum of all three processes. The energy of the photon determines which interaction dominates.

Photoelectric effect

The photoelectric effect occurs when all of the energy of the incident photon is transferred to an atomic electron and the electron is ejected from the atom. The photoelectric effect is important for photons below about 200–300 keV interacting with all but the lightest elements.

In the photoelectric effect, a photon interacts with an atom in the material and is completely absorbed. As a result, one of the orbital electrons is excited and ejected from the atom. The ejected electrons are called photoelectrons. The photoelectric effect occurs with the atom as a whole and cannot take place with free electrons. The kinetic energy of the ejected photoelectron (T_{e^-}) is the difference between the energy of the incident photon (E_γ) and the binding energy of the electron (E_b):

$$T_{e^-} = E_\gamma - E_b \quad (1)$$

After the photoelectrons are ejected, the atom is left behind with a vacancy in one of its bound shells. The vacancy is quickly filled by a free electron being captured from the surrounding medium and/or by electrons being rearranging from other shells of the atom. This process of vacancy filling generates one or more X-rays with characteristic energies. In some fraction of the cases, the excess energy is transferred to another electron bound to the atom. The excited electron is in turn ejected from the atom, resulting in an Auger electron.

The photoelectric process is the primary mode of interactions for photons at low energies (~ 100 keV). The interaction probability, τ , is difficult to calculate but rather shown empirically to increase rapidly with decreasing photon energy and increasing atomic number, Z , of the absorber material:

$$\tau \propto \frac{Z^n}{E_\gamma^{3.5}} \quad (2)$$

where n varies between 4 and 5 depending on E_γ . The strong Z dependence of photoelectric effect is the reason for the use of high- Z materials such as lead in gamma-ray shields.

Compton scattering

At energies between keV's to tens of MeV's, photons interacting with electrons will undergo a Compton scattering, an elastic process where a fraction of the energy of the incident photon is transferred to the electron, resulting in the scattered photon having lower energy than it had before the interaction. As in all such collisions, the kinematics of the scattering process conserve energy and linear momentum. In the limit that the photon energy is large compared with the orbital energies of the loosely bound outer atomic electrons (usually a good approximation), the electron can be regarded as free and at rest.

The basic principle of Compton scattering is shown in Fig. 1. The incoming photon with energy $E_\gamma = h\nu$ scatters off of an electron and is deflected with energy $E_\gamma' = h\nu'$ by an angle θ with respect to its original direction ($h = 6.626 \times 10^{-34}$ J $\cdot$ s is the Planck

Fig. 1 Schematic of Compton scattering. By Reina Maruyama.

constant and ν is the frequency of the photon). The electron now has some momentum and emerges as a recoil electron. Using conservation of linear momentum and total energy, we arrive at the Compton scattering formula

$$E'_\gamma = \frac{E_\gamma}{1 + (E_\gamma/m_e c^2)(1 - \cos \theta)} \quad (3)$$

where $m_e c^2 = 0.511$ MeV is the rest mass energy of the electron. For small scattering angles θ , very little energy is transferred. At the other extreme of $\theta = 180^\circ$, the energy of the scattered photons is at a minimum and is roughly $m_e c^2/2 \approx 0.25$ MeV for incident photons with energies much larger than 0.511 MeV.

The probability of Compton scattering at an angle θ is described by the Klein-Nishina formula for the differential cross section per electron:

$$\frac{d\sigma_c}{d\Omega} = r_0^2 \left(\frac{1}{1 + \alpha(1 - \cos \theta)} \right)^2 \left(\frac{1 + \cos^2 \theta}{2} \right) \left(1 + \frac{\alpha^2(1 - \cos \theta)^2}{(1 + \cos^2 \theta)[1 + \alpha(1 - \cos \theta)]} \right) \quad (4)$$

where $d\Omega$ is the solid angle around θ , $\alpha = E_\gamma/m_e c^2$ and r_0 is the so-called classical electron radius defined as $r_0 = e^2/4\pi\epsilon_0 m_e c^2 = 2.818 \times 10^{-13}$ cm. The parameter r_0 is merely a convention and has nothing to do with the size of the electrons. The Klein-Nishina cross section is peaked forward strongly for scattering at higher gamma energies. The experimental data agree perfectly with Eq. (4) and is among the most convincing successes of quantum theory.

To calculate the total cross section of photons, we integrate Eq. (4) over all $d\Omega$ to obtain

$$\sigma_c = \frac{\pi r_0^2}{\alpha} \left(\left[1 - \frac{2[\alpha + 1]}{\alpha^2} \right] \ln(2\alpha + 1) + \frac{1}{2} + \frac{4}{\alpha} - \frac{1}{2(2\alpha + 1)^2} \right) \quad (5)$$

As the energy of the photon increases, the total cross section decreases and the probability of scattering becomes more forward peaked.

Pair production

If the energy of a photon is greater than twice the rest mass of an electron, i.e., $2m_e c^2 = 1.02$ MeV, the photon can interact with the electromagnetic field of a nucleus and undergo pair production to create an electron-positron pair. The photon disappears completely, and its energy is transformed into the rest masses and kinetic energies of the electron-positron pair. The total kinetic energy of the electron-positron pair is

$$T_{e-} + T_{e+} = E_\gamma - 2m_e c^2 \quad (6)$$

where the E_γ is the energy of the incoming photon and T_{e-} and T_{e+} are the kinetic energies of the electron and positron, respectively. Once formed, the electron and positron will propagate in the medium and lose energy by Coulomb interactions with the atomic electrons bound in the medium. The positron will slow down until it reaches thermal energies and eventually annihilate with an electron. Two photons that travel in opposite directions are produced as secondary products of this interaction, each with an energy of $m_e c^2$. The probability of pair production increases sharply as gamma-ray energy approaches several MeV but is especially important for energies above 4–6 MeV and increases approximately as the square of the absorber atomic number. Pair production can also occur in the electromagnetic field of electrons, however the minimum energy required for such a process is four times the rest mass of an electron.

Total cross sections and attenuation coefficients for photons

The interaction of photons with matter will proceed by all possible mechanisms including photoelectric effect, Compton scattering, and pair production as described above, as well as less prominent mechanisms such as Rayleigh scattering and photonuclear interactions. To quantify the interactions probability of photons with matter, we use total cross section (σ_{total}), linear attenuation coefficient (μ), and mass attenuation coefficient (μ/ρ). Units that are usually used to quantify these parameters are barns [$1\text{b} = 10^{-24} \text{ cm}^2$] for cross sections (σ), [cm^{-1}] for linear attenuation coefficient (μ), and [$\text{cm}^2 \text{ g}^{-1}$] for mass attenuation coefficient (μ/ρ).

The total cross section per atom, σ_{total} , is defined as the sum of the cross sections of the individual possible interaction mechanisms. Fig. 2 shows the total cross section and each of its components for photons interacting with lead and carbon as a function of energy. The figure shows how the cross section is dominated by the photoelectric effect at low energies (e.g., below about 10 keV for carbon and 100 keV for lead), Compton scattering at around 1 MeV, and pair production above 10 MeV. More detail can be found in Tanabashi et al. (2018). Data for photon cross sections can be found in Berger et al. (2010).

The total linear attenuation coefficient, μ , is defined as the total probability per unit length that an incoming photon is removed from the incoming beam. The total linear attenuation coefficient μ is the sum of the respective linear absorption coefficients for photoelectric absorption ($\mu_{\text{photoelectric}}$), Compton scattering (μ_{Compton}), and pair production ($\mu_{\text{pair production}}$):

$$\mu = \mu_{\text{photoelectric}} + \mu_{\text{Compton}} + \mu_{\text{pair production}} \quad (7)$$

Fig. 2 Photon total cross sections as a function of energy in carbon and lead showing the contributions from photoelectric effect ($\sigma_{p.e.}$), Compton scattering (σ_{Compton}), pair production in nuclear field (κ_{nuc}), and pair production in electron field (κ_e), as well as less prominent contributions such as Rayleigh scattering (σ_{Rayleigh}) and photonuclear interactions, most notably the Giant Dipole Resonance ($\sigma_{g.d.r.}$). Figure from Tanabashi M, et al. (Particle Data Group) (2018). *Physical Review D* 98: 030001 with data from Berger MJ, et al. (2010) *XCOM: Photon Cross Sections Database, NIST Standard Reference Database 8 (XGAM)*, <https://doi.org/10.18434/T48G6X>.

The linear absorption coefficient takes into account the number of nucleons and electrons available per unit length while cross section is the probability for interaction per atom. For example, Compton scattering, μ_{Compton} is proportional to σ_c described in Eq. (5) by

$$\mu_{\text{Compton}} = \sigma_c N Z \quad (8)$$

where Z and N are the atomic number and number of atoms per unit volume of the material respectively.

The photon beam intensity I in ($\text{cm}^{-2} \text{s}^{-1}$) of transmitted photons through a medium of thickness x , given initial beam intensity I_0 is

$$I = I_0 e^{-\mu x} \quad (9)$$

The average distance traveled in a medium before an interaction takes place is characterized by the mean free path, $\lambda = 1/\mu$. Typical values of λ range from a few mm to tens of cm in solids for typical gamma-ray energies.

Although linear attenuation coefficients are convenient for engineering applications, they are proportional to the absorber density, ρ , which depends to some extent on the physical state of the material. Therefore, attenuation coefficients are often given as the mass attenuation coefficient (μ/ρ) which is the ratio of the linear attenuation coefficient to the density of a material, ρ :

$$\text{mass attenuation coefficient} = \frac{\mu}{\rho} \quad (10)$$

Mass attenuation coefficients do not depend on the physical state of a given absorber and has the units of $[\text{cm}^2 \text{g}^{-1}]$. The mass attenuation coefficient is proportional to the total photon interaction cross section per atom as:

$$\frac{\mu}{\rho} \left[\frac{\text{cm}^2}{\text{g}} \right] = \sigma_{\text{tot}} \left[\frac{\text{cm}^2}{\text{atom}} \right] \frac{N_A \left[\frac{\text{atoms}}{\text{g} \cdot \text{atom}} \right]}{M \frac{\text{g}}{\text{atom}}} = \sigma_{\text{tot}} \left[\frac{\text{b}}{\text{atom}} \right] \cdot N_A / M \cdot 10^{-24} \quad (11)$$

The mass attenuation coefficient of a mixture of elements can then be calculated from

$$\left(\frac{\mu}{\rho} \right)_c = \sum_i w_i \left(\frac{\mu}{\rho} \right)_i \quad (12)$$

where w_i factors are the weight fraction of element i in the compound or mixture.

Interaction of charged particle with matter

In this section, we will discuss the interactions of charged particles such as electrons, positrons, protons, and ions with matter. Interaction of charged particles with matter occur mainly through the Coulomb interactions with the orbital electrons in the medium. Charged particles also interact with atomic nuclei, however the Coulomb field of the nucleus is well shielded by the orbital electrons therefore such interactions are small and are negligible for most practical applications. The exception would be when those trajectories would bring the incident particle close to the nucleus.

We first discuss the interaction of heavy charged particles including protons, alpha particles, and other ions that have masses much greater than that of an electron. Their trajectories are mostly linear and simple. We will then discuss the interaction of light charged particles, in other words electrons and positrons, with matter.

Interactions of heavy charged particles in matter

As heavy charged particles such as protons, alpha particles, and ions travel through matter, they interact—via the Coulomb force—primarily with the negatively charged orbital electrons bound to the atoms in the medium. In these interactions, the electrons are excited into higher orbital states (a process called “excitation”) or may even be ejected from the atom (a process called “ionization”).

The Coulomb force has a $1/r^2$ dependence and can reach far. Therefore, a charged particle traveling through matter interacts with many electrons simultaneously. It loses energy gradually and continuously as it travels through the medium, until it has lost all of its energy. The total distance that it travels is called the range of the particle. The range is determined by the type and energy of the particle and the type of material it encounters. The mean range is defined as the range at which one-half of the particles have longer ranges and the other half shorter.

Because the mass of a heavy charged particles is much larger than the mass of an electron, each collision results in loss of only a small fraction of the particle’s kinetic energy. The change of momentum of the heavy charged particle is thus negligible. A large number of collisions is needed for a heavy charged particle to come to rest in a medium.

Stopping power

The linear stopping power, sometimes called specific energy loss, for charged particles in a given material is defined as the differential energy loss of the particle in the material ($-dE$) divided by the differential path length (dx). The energy loss of charged particles in matter was first calculated by Bohr using classical mechanics in 1913 and later by Bethe (1930), then by Bloch (1933) using quantum mechanics (Bohr, 1913; Bethe, 1930; Bloch, 1933). The small amount of energy lost ($-dE$) by a particle in the medium per unit length (dx) is, to a good approximation, by what we now call the Bethe equation:

$$-\frac{dE}{dx} = \frac{4\pi e^4 z^2}{m_0 v^2} N Z \left[\ln \frac{2m_0 v^2}{I} - \ln \left(1 - \frac{v^2}{c^2} \right) - \frac{v^2}{c^2} \right] \quad (13)$$

where v and ze are the velocity and charge of the incoming charged particle respectively, N and Z are the number density and atomic number of the atoms in the absorber medium, m_0 the electron mass, e is the electric charge, and I is the mean excitation and ionization potential of the atoms of the absorber the particle is going through. The quantity, $-dE/dx$ is called the stopping power.

In applications related to nuclear energy production, the charged particles are typically nonrelativistic ($v \ll c$). Therefore, v^2/c^2 is small and the expression inside the square brackets in Eq. (13) varies slowly with the particle’s energy. The stopping power varies as $1/v^2$ to a good approximation: the slower the incoming particle, the more energy it loses per unit length of travel inside the medium. dE/dx is proportional to z^2 , therefore incoming particles with greater charge z will have greater stopping power (for example, alpha particles will lose more energy per unit length than protons do). Absorber materials with larger NZ will exert larger stopping power. NZ represents the electron density of the absorber, and materials with high atomic number and high densities have larger stopping power.

In practice, it is useful to describe the energy loss in media in terms of ρx , the product of density of the medium ρ and distance traveled x . ρx is typically given in $[\text{g cm}^{-2}]$. It can be measured experimentally by taking the ratio of the mass and the area of the medium. The stopping power typically found in the literature is:

$$\frac{dE}{d(\rho x)} = \frac{1}{\rho} \frac{dE}{dx} \quad (14)$$

As noted in Eq. (13), the stopping power for particles much heavier than electrons depends on its charge and speed and does not depend on the mass of the particle.

By integrating Eq. (13) we can calculate the range R , the total distance that a particle of given initial kinetic energy E_0 travels in a given medium. To put it another way, to a good approximation, R is the average path length traveled by a charged particle as it slows down to rest. The range is given by

$$R = \int_{E_0}^0 \left(-\frac{dE}{dx} \right)^{-1} dE \quad (15)$$

where E is the kinetic energy of the particle along its path in the medium. Because the particles lose energy through scattering by atomic electrons, the range depends inversely on the density, and the product ρR in units of g cm^{-2} is often a more useful quantity than R (note: both R and ρR are referred to as “range” in the literature—check the units to determine which one is being used). Fig. 3 shows the range-energy relationship for protons and α particles in air, water, and graphite in terms of ρR . For database on range and energy for other particles and materials, refer to Berger et al. (2017).

Energy loss characteristics: The Bragg curve and energy straggling

As a heavy charged particle travels through matter, it loses its energy to the surrounding medium. The stopping power ($-dE/dx$) increases roughly as $1/E$ for most of its track as shown in Eq. (13). Fig. 4 shows the stopping power along the track of an alpha particle with an initial energy of 5.49 MeV traveling through air. As the energy of the particle decreases, the $1/E$ dependence causes a pronounced peak in the stopping power where the energy loss of the particle becomes significant. For the case of an alpha particle in air as shown in Fig. 4, this occurs at around 3.5 cm. The peak is called a Bragg peak after William Henry Bragg who discovered it in 1903. Beyond the Bragg peak and near the end of its track, the charged particle picks up electrons from the surrounding material and the $1/E$ dependence is no longer valid. As a result, the stopping power, i.e., $-dE/dx$ falls off rapidly.

The energy loss of a specific charged particle as it goes through a medium is a stochastic process and the details of the microscopic interactions of a specific charged particle vary somewhat randomly. After a beam of monoenergetic charged particles has passed

Fig. 3 Range-energy curves for protons and alpha particles in air (dry, near sea level), water (liquid), and graphite (density = 1.7 g/cm^3). Data from Berger MJ, et al. (2017) *Stopping-Power & Range Tables for Electrons, Protons, and Helium Ions*. <https://doi.org/10.18434/T4NC7P>.

Fig. 4 Bragg curve: stopping power, i.e., specific energy loss, vs. path length for a 5.49 MeV alpha track in air. Figure by Helmut Paul-public domain, <https://commons.wikimedia.org/w/index.php?curid=770220>.

through a given thickness of the absorber material, there will be a spread in the particles' energies. The spread, or the width of the energy distribution, is a measure of "energy straggling." Energy straggling varies with the distance along the particle track. The distribution narrows again near the end of the track after the mean particle energy has greatly been reduced.

These phenomena are exploited in particle therapy of cancer. The presence of Bragg peak and energy straggling can concentrate the effect of light ion beams on the tumor being treated while minimizing the effect on the surrounding healthy tissue. A monoenergetic proton beam with the sharp peak is widened by increasing the spread of energies, so that a larger tumor volume can be treated. This can be achieved by using variable thickness attenuators like spinning wedges.

Interactions of electrons with matter

As in the case of heavy charged particles, electrons and positrons also interact with atomic electrons via the Coulomb force. However, there are several significant differences owing to the electron's smaller mass. As described in the previous section, heavy charged particles travel in near straight lines since they are much heavier than the electrons they interact with. However, we now have electrons interacting with electrons, in other words, their masses are the same so the incoming electrons will: (1) travel at relativistic speeds, particularly those that were emitted in β decays; (2) experience large deflections; (3) transfer a large fraction of the initial energy to the other electron; and (4) emit electromagnetic radiation (called bremsstrahlung radiation) as they experience large deceleration.

There are two primary energy loss mechanisms for electrons in matter. At energies below a critical energy, $E_c \approx 600 \text{ MeV}/Z$, energy loss via excitation and ionization of the bound electrons dominate (here, Z is the charge number of the atoms in the medium). Above E_c , energy loss is primarily via radiation. We discuss the interactions in the two energy regions below.

Ionization region ($E < E_c$)

The energy loss mechanism in the ionization region ($E < E_c$) is similar to what was described for heavy particles in section "Interactions of heavy charged particles in matter", and Eq. (13) can be used with small modifications. There is one significant difference: when heavy charged particles interact with electrons in the medium, each collision produces minimal change to their momentum. When electrons interact with other electrons, their momentum can undergo significant change since their masses are the same.

Radiation region ($E > E_c$)

There is a significant difference between the energy loss rate of electrons and heavier charged particles in the radiation region, $E > E_c$. When an electron passes by an atomic nucleus, its trajectory can be deflected as a result of Coulomb scattering with the nucleus. A charged particle that is accelerating or decelerating in an electric field will emit energy as electromagnetic radiation known as bremsstrahlung radiation (literally translated from German to English as "braking radiation"). The probability of emission of bremsstrahlung radiation is inversely proportional to the square of the mass of the particle. As a result, bremsstrahlung radiation is much more of a significant source of loss of energy for electrons than it is for protons or other heavy charged particles.

The energy of bremsstrahlung radiation is equal to the difference between the kinetic energy of the electron before and after the deflection, and is proportional to $(E_0/m_e c^2)^4$ where E_0 and m_e are the energy and mass of the incoming particle (electron in this case) respectively. Its energy ranges from zero to the maximum kinetic energy of the bombarding electrons depending on how much the

Table 1 Critical energy E_c and radiation lengths X_0 in (g cm^{-2}) and (cm) for selected materials.

Material	Z	Density (g cm^{-3})	Critical energy (MeV)	Radiation length	
				(g cm^{-2})	(cm)
H ₂ (liquid)	1	0.071	340	62.8	887

Data from Tanabashi M, et al., (Particle Data Group) (2018) *Physical Review D: Particles and Fields* 98: 030001.

electrons are influenced by the electric field of the nucleus, therefore when taken as an ensemble, can produce the full spectrum of energies between 0 and E_{max} .

The radiative energy loss for large electron energies is

$$-\left(\frac{dE}{dx}\right)_{rad} \approx \frac{E}{X_0} \text{ or } E = E_0 e^{-x/X_0} \quad (16)$$

where X_0 is the radiation length given in either g cm^{-2} or cm. The radiation length (also called attenuation length) is the distance over which the bombarding electrons lose energy by a factor of $1/e$. A few values of X_0 and critical energy E_c are provided in Tanabashi et al. (2018) and given in **Table 1**.

When the photons generated by bremsstrahlung radiation have energies higher than 1 MeV, they can successively produce electron-positron pairs via pair production. The average distance that a photon travels before it produced electron-positron pair (X_p) is related to the radiation length (X_0) by $X_p = (9/7)X_0$. The secondary electron will successively produce more electron-positron pairs creating a shower. The number of electrons rapidly increase in the beginning as they pass through the target medium. As the shower process proceeds, the average energy per electron becomes smaller, and ceases when pair production is no longer energetically possible.

Radioactive decay background

A nuclear reaction typically involves an incident particle that penetrates the nucleus and induces a change that results in a different nucleus and exit particle. However, it is possible that a nucleus spontaneously changes itself into a different state or type of nucleus along with some emitted particle. Nuclei that can undergo this spontaneous change are termed “unstable” although the time scale may run from pico-seconds to many millennia.

Because the emitted particle has its birthplace in the nucleus, its energy is normally sufficiently high to be able to cause ionizations in the surrounding materials it encounters. The most common particles are the beta particle (an electron), an alpha particle (a helium nucleus), a gamma ray (a high energy photon, or a neutron. It is the effect of these emitted radiations in the surrounding material that are often of most concern to us since they can result in beneficial or deleterious physical changes.

This unstimulated change is a manifestation of the probabilistic nature of quantum mechanics. We associate this decay process for each unstable nucleus as having a constant probability per time λ for a decay, which naturally leads to the radioactive decay law for the population $N(t)$ of radioactive nuclei (Knoll, 2010):

$$\frac{dN}{dt} = -\lambda N(t)$$
$$N(t) = N(t=0)e^{-\lambda t}$$

The term λN represents the rate of decay of the material having $N(t)$ radioactive nuclei, and is referred to as the *activity* of the material. Activity is measured in units of disintegrations per second (i.e., 1 Bq = 1 dps), or in a more practical unit, in units of *Curies* (e.g., 1 Ci = 3.7×10^{10} dps).

While the activity is a measure of the rate of radioactive decay of a material, it tells us nothing about the impact of those decays on the surrounding materials. Other units must be defined that reflect the physical impact of these emitted radiations. For physical damage to most materials, we care about the energy deposited in a unit mass of the material, and the associated measurement units are *rads* (1 rad = 100 ergs/g) or *Grays* (1 Gy = 1 J/kg). For biological impact, we must also account for the nature of the cellular damage, and a unit that accounts for this is defined as either the *rem* (a rad with a biological impact factor) or a *Sievert* (a Gray with the same biological impact factor). Just to provide a context for the scale of the units, one might be concerned with electrical deterioration of a microchip if it receives ~ 1 Mega-rad of dose, or a fatal dose of ~ 500 rem delivered to a person. But most exposures encountered in daily life are $\sim 10^{-3}$ of a rad or rem, making exposure to natural radioactivity generally considered rather innocuous compared to commonly encountered risks. However, such may not be the case around intense, man-made sources of radiation, such as within nuclear power plants, as discussed below.

Natural radioactivity

Radiation sources are usually classified as either natural or man-made. Natural ionizing radiation is ubiquitous because our Earth contains naturally radioactive isotopes that have survived the ~ 4.5 billion years since the earth was formed. Only a few lighter radioactive isotopes have survived, namely beta emitters of potassium-40 and rubidium-87. However, the heavier elements, i.e., the actinides, synthesized from repeated neutron capture and beta decay, have isotopes with half-lives on the scale of planetary evolution. Since these isotopes are prevalent in the Earth's crust, and all physical objects are derived from there, one cannot avoid some exposure to radioactive sources. Hence the familiar phrase “I’m radioactive and you are too.”

Whereas the midweight nuclei tend to decay by beta emission, these heavier nuclei prefer to decay through a succession of alpha emissions (with the occasional beta emission included) until they reach a stable endpoint. These long decay chains, which originate from either uranium-238, uranium-235, or thorium-232, give rise to a number of naturally occurring radioactive isotopes, such as the radon-222 noble gas of environmental concern.

Another source of natural radiation comes from the natural background of cosmic rays that interact in the atmosphere and form radioactive isotopes that enter our ecosystem. Most notable among these are carbon-14 produced by the interaction of neutrons and atmospheric nitrogen-14. In general, these cosmic sources of radiation are too small to be of biological interest under our protective atmosphere.

Man-made radioactive sources from neutron capture

Neutrons provide an easy means to create more interesting and substantial radioactive source. Without any electrical charge, they can enter the positively charged nucleus without hindrance. And with the addition of a neutron, the strong nuclear force within adds substantial energy to the enhanced nucleus that can permit a subsequent nuclear reaction. The resulting daughter nuclei are often-times unstable, and may lead to a further chain of radioactive decays. Such a process might be written as:

where n signifies a neutron, X is the target nucleus, X^* is the excited nucleus after absorbing the neutron, and Y and b represent the daughter nucleus Y and emitted particle b that emerge from the nuclear reaction. A more compact way to write this is $X(n, b)Y$, where we would classify the reaction type as (n, b) (Table 3 shows more general nuclear reactions of types (a, b)).

As a common example, exposing naturally occurring cobalt-59 to neutrons produces the radioactive cobalt-60 sources used for a variety of applications, including food sterilization or radiation therapy. Commercially viable radioactive materials can thus be made by exposing stable, naturally occurring isotopes to neutrons that are produced in either a research reactor or a dedicated accelerator source.

Radioactive sources and applications

Radioactive sources find common uses in industrial processes (e.g., thickness or moisture gauges (also known as “Troxler” gauges), sterilization, oil well exploration, radiography) as well as in space (e.g., thermoelectric generators) and medical applications (e.g., blood irradiators, brachytherapy, radiation therapy). Because a decaying radioactive source cannot be turned off, there has been a trend to transition to accelerator-based sources if the local infrastructure can support this more advanced technology. For example, modern radiation therapy centers have replaced cobalt-60 sources with electron (or even heavier ion) accelerators to deliver therapeutic doses of radiation. Furthermore, the accelerator-based generators of radiation do not carry the same level of security risks as the more portable radioactive sources.

Because of the potential health and environmental risks, most countries maintain regulatory controls over portable radioactive sources (and, to a lesser extent, accelerator-based sources of radiation). The International Atomic Energy Agency (IAEA) maintains a program (cf. IAEA, 2005) to help countries categorize and manage their inventory of radioactive sources. These include a surprisingly large number: Sr-90, Pu-238, Co-60, Cs-137, Se-75, Ir-192, Yb-169, Tm-170, Am-241, Pu-239/Be, Cf-252, Ra-226, I-125, Au-198, Kr-85, Pm-147, Cm-244, Ra-226, Cd-109, Gd-153, Po-210, Mo-99, I-131, Fe-55, Cd-109, Ni-63, H-3, Ru/Rh-106, Pd-103, Ge-68, and P-32. Table 1, drawn from these IAEA publications, lists some of these isotopes and their various applications (Ferguson et al., 2003).

Many people are familiar with smoke detectors although they may not realize the ionization-type of detector contains a very small amount (~ 1 microCurie) of radioactive Am-241. An alternate type, the photoelectric type, avoids this internal radioactive source, but is less sensitive to fast-burning fires. Combination units are available, but are more costly and thus less widely used. Because of what some consider an overabundance of concern, some communities now forbid installing ionization-type smoke detectors despite their safety advantages (U.S. Nuclear Regulatory Commission, 1979).

In addition to the IAEA, radioactive sources and their applications are also tabulated by the World Nuclear Association (n.d.-a). Within the United States, the Nuclear Regulatory Commission regulates and maintains information on current and former vendors of sealed sources and devices (The U.S. Nuclear Regulatory Commission, n.d.). Interestingly, a registry of the current and inactive sources located within the country is available.

The United States Department of Energy maintains an isotope development program (The U.S. Department of Energy Isotope Program, n.d.) whose goal is to produce *radioactive and enriched stable isotopes that are deemed critical or are in short supply*. A sample of the output from this national production network is shown in Fig 1. The DOE program matches radioactive source customers to source suppliers (nuclear reactors and accelerators) to satisfy needs not met by existing commercial suppliers.

As described above, much of the flow of commercial radioactive sources originates from dedicated low power nuclear reactors, and then is passed to commercial entities that convert the radioactive material into a viable product. A 2003 flowchart shows the global activity involvement in Fig. 2.

Radioactive materials as a byproduct of fission

One type of neutron induced reaction relevant to this encyclopedia is nuclear fission. For this reaction, the reaction products Y and b are termed fission products that are highly radioactive. In addition to the fission fragments, more neutrons are released during the reaction that perpetuate the reaction chain, leading to a buildup of highly radioactive nuclei. While each fission reaction immediately yields a large amount of energy (200 MeV) that can be used for electric power generation, a side effect is the initial highly radioactive waste products (e.g., neutron-activated structural materials along with fission products and their progeny) that remain in the core and persist after the reactions are terminated. While these fission products contain some valuable isotopes that could be extracted, with the exception of molybdenum-99, this has not proven to be cost-effective. Instead, the remnants from the generation of electric power from nuclear fission are a highly radioactive mixture of isotopes that must be managed.

Table 1 Applications using radioactive sources.

<i>Practice or application</i>	<i>Radioisotope</i>	<i>Typical radioactivity level (Curies)</i>
<i>Category 1</i>		
Radioisotope thermoelectric generators	Sr-90	30,000–300,000
Teletherapy	Co-60	1350–27,000
	Cs-137	13,500
Blood irradiation	Cs-137	50–2700
Industrial radiography	Ir-192	3–250
	Co-60	3–250
Sterilization and food preservation (irradiators)	Co-60	2700–11,000,000
	Cs-137	2700–11,000,000
Other irradiators	Co-60	27–27,000
	(Cs-137 rare)	27–27,000
<i>Category 2</i>		
High dose rate remote after loading brachytherapy	Co-60	0.27
	Cs-137	0.8×10^{-6} – 2.7×10^{-4}
	Ir-192	11
Low dose rate brachytherapy (manual or remote)	Cs-137	0.0014–0.014
	Ra-226	0.0008–0.008
	Co-60	0.0014–0.014
	Sr-90	0.0014–0.04
	Pd-103	0.0014–0.04
	Cs-137	0.027–2.7
Well logging	Am-241/Be	0.027–22
	(Cf-252 rare)	1.4
Level gauge thickness gauge conveyor gauge	Cs-137	0.27–27
	Co-60	0.027–0.27
Moisture/density detector (portable, mobile units)	Am-241	0.27–1.1
	Am-241/Be	0.0027–0.054
	Cs-137	Up to 0.0011
	Ra-226/Be	0.04
	(Cf-252 rare)	0.08
<i>Category 3</i>		
Level gauge density gauge	Cs-137	0.0027–0.54
	Co-60	0.0027–0.027

Surprisingly, most of these radioactive isotopes are relatively short-lived. In fact only seven have half-lives longer than 25 years, and, of those, only strontium-90 and cesium-137 have relevant half-lives (approximately 30 years) to be of health concern. Rather, the troublesome part of nuclear spent fuel is the low radioactivity of very long-lived transuranic isotopes produced from neutron absorption. This can be seen in the figure below which plots the activity per unit mass as a function of the time after shutdown. Determining an acceptable level of residual radiation, and thus defining the waiting time in isolation, remains an open question for society.

Before we close our discussion of radioactive sources produced by nuclear energy, we note an alternative measure of generating nuclear energy is through fusion. One of the main advantages of this mode of generating nuclear energy is avoiding the production of the very long-lived transuranic isotopes shown in Fig. 3. Thus, while fusion machines may actually produce larger volumes of radioactive materials (less so if neutrons are not released in the fusion reaction) the radioactive byproducts tend to be of shorter timescales and less objectionable to the public.

Accelerator based

With a limited number of nuclear reactors available to produce customized radioactive sources, accelerators are now widely used to produce many of the desired isotopes. Both cyclotrons and linear accelerators are employed to accelerate charged particles (protons,

deuterons, alpha particles, or heavy ions) onto a target that is chosen to induce a particular nuclear reaction. The critical production parameters involve the incident particle energy (with lower energy requirements (<30 MeV) allowing the more compact cyclotron geometry) and beam current (defining the production rate). Commercial, university, and governmental entities operate accelerator facilities to produce specific radioisotopes.

Commercial entities (e.g., Nordion or IBA Radiopharma Solutions) usually operate lower power accelerators and have found a viable market as a reliable source of radiopharmaceuticals for clinic practice. A typical commercial accelerator might deliver a 1 mA beam of 30 MeV particles. In contrast, university hospitals typically operate even lower energy cyclotrons to produce quite short-lived positron emitters (C, F, N, O isotopes) used onsite in their nuclear medicine clinics for positron emission tomography (PET) imaging. Larger university accelerators are often associated with nuclear physics investigations, but these can also be adapted to produce radioisotopes. For example, the production of At-211 requires an alpha particle beam incident on a bismuth target—a configuration more akin to a physics experiment.

Government accelerators are also operated to provide a source of radioactive materials for societal use. They often can operate at higher energies and can produce either relatively rare isotopes being explored for new applications, isotopes unable to be produced through more conventional machines, or rarely needed isotopes that are essential in high priority situations. Table 2 provides a subset of international accelerators used for producing isotopes.

A major commercial and societal driving force for isotope production involves medicine, and Table 3 shows a list of commonly used isotopes and their production mechanisms. Accelerators would be used for the reactions in which the incident particle is charged, otherwise nuclear reactors would be used. The radiation emitted from these sources can be selected to penetrate deep into the body (for diagnostic testing) or to selectively destroy diseased cells (for therapy). The emergence of theranostics, i.e.,

Table 3 Radioisotopes of interest in medicine and their major production routes.

Isotope	T1/2	Reaction	Comment/availability
^{44}Sc	3.93 days	$^{44}\text{Ca}(\text{p},\text{n})$	Low energy protons
^{47}Sc	3.35 days	$^{50}\text{Ti}(\text{p},\alpha)$	Enriched target needed
^{64}Cu	12.7 h	$^{64}\text{Ni}(\text{p},\text{n})$	University network
^{67}Cu	3.79 days	$^{70}\text{Zn}(\text{p},\alpha)$	Enriched target needed/spall. Mo
^{67}Ga	3.62 days	$^{70}\text{Zn}(\text{p},2\text{n})$	Commercial
^{68}Ga	1.13 h	$^{68}\text{Zn}(\text{p},\text{n})$	Low energy protons/generator
^{68}Ge	271 days	$^{68}\text{Ga}(\text{p},2\text{n})$	Used to make ^{68}Ga via generator
^{72}As	26.0 h	$^{72}\text{Ge}(\text{p},\text{n})$	Low energy protons
^{77}As	38.8 h	$^{80}\text{Se}(\text{p},\alpha)$	Low energy protons
^{76}Br	16.2 h	$^{76}\text{Se}(\text{p},\text{n})$	Enriched target needed
^{77}Br	57.0 h	$^{\text{nat}}\text{Mo}(\text{p},\text{spall})$	High energy protons
^{86}Y	14.7 h	$^{86}\text{Sr}(\text{p},\text{n})$	University network
^{90}Y	64.1	^{90}Sr generator	Commercial
^{89}Zr	3.27 days	$^{89}\text{Y}(\text{p},\text{n})$	University network
$^{99\text{m}}\text{Tc}$	6.0 h	^{99}Mo generator	Commercial
^{111}In	67.2 h	$^{112}\text{Cd}(\text{p},2\text{n})$	Commercial
$^{117\text{m}}\text{Sn}$	14.0	$^{116}\text{Cd}(\alpha,3\text{n})$	High energy alphas
^{123}I	13.2	$^{124}\text{Xe}(\text{p},2\text{n})$	Commercial
^{124}I	4.18 days	$^{124}\text{Te}(\text{p},\text{n})$	University network
^{131}I	8.0 days	Fission product	Commercial
^{149}Tb	4.12 h	$^{197}\text{Au}(\text{p},\text{spall})$	Online isotope separator
^{152}Tb	17.5 h	$^{197}\text{Au}(\text{p},\text{spall})$	Online isotope separator
^{161}Tb	6.91 days	$^{197}\text{Au}(\text{p},\text{spall})$	Isotope separator
^{177}Lu	6.65	$^{176}\text{Lu} + \text{n}$	Commercial via n capture
		$^{180}\text{Hf}(\text{p},\alpha)$	proton reaction for high specific activity
$^{195\text{m}}\text{Pt}$	4.0	n capture	
^{198}Au	2.69	n capture	High specific activity from $^{198}\text{Pt}(\text{p},\text{n})$
^{211}At	7.2 h	$^{209}\text{Bi}(\alpha,2\text{n})$	University network
^{211}Rn	14.6 h	$\text{U/Th}(\text{p},\text{spall})$	High energy/ ^{211}At source
^{223}Ra	11.4 days	Decay chain	Commercial
^{225}Ac	10.0 days	Multiple routes	Demand outstrips supply

the simultaneous execution of both therapy and diagnostics, offers the promise of improved outcomes based on patient-specific responses. For this modality, pairs of radioactive isotopes are chosen to accomplish the two tasks of locating and then treating. Since the chemistry for isotopes of the same element is the same (e.g., copper-64 is a positron emitter for imaging and copper-67 is an

electron emitter for therapy), one delivery pharmaceutical can be used to perform both tasks simultaneously. The exploration and development of these medically important isotopes has created a vibrant research area.

Neutron sources

In section *Man-made radioactive sources from neutron capture*, we mentioned that neutrons provide a convenient way to perturb the nucleus and induce a reaction. While nuclear reactors provide a copious supply of neutrons, more convenient and accessible sources have also been developed. These sources are used in density and moisture gauges, oil well exploration, neutron radiography, health physics instrument calibration, and physics research, among others. With the contemporary interest in homeland security and nonproliferation, these alternate sources have received renewed attention.

To produce free neutrons (other than from fission in a nuclear reactor), one can either (1) use nuclei that naturally fission as their radioactive decay mode, or (2) induce a nuclear reaction in which one product is a neutron (NRC, n.d.).

The first method mentioned, known as spontaneous fission, occurs in some particularly heavy nuclei with even numbers of neutrons and protons. Some examples include plutonium-238, curium-242, and curium-244, but by far the most commonly used neutron source is californium-252.

Californium-252 is quite convenient as a neutron source because its high specific radioactivity means that small amounts of the material are sufficient to produce a significant rate of neutron emission ($\sim 2 \times 10^{12}$ n/s/g). Unfortunately, Cf-252 has a relatively short half life of 2.6 years, so these sources weaken over time, and must ultimately be replaced. The radioactive material is usually doubly encapsulated in stainless steel, but still will occupy only a few cm³ or less. This makes them quite convenient and portable. Because the neutrons are produced by fission, they will have a characteristic average energy (~ 2 MeV) that proves to be so useful in the applications mentioned above. When a softer distribution of energies is needed for an application, the source can be buried inside a designed set of materials to tailor the fission neutron energy distribution.

The second method of producing neutrons involves inducing a nuclear reaction. As a target material, the beryllium nucleus is particularly attractive because beryllium-9 has one very loosely attached neutron. By striking that nucleus with an alpha particle produced by an alpha decay, a nuclear reaction can take place that produces a carbon-12 nucleus and a free neutron. By intimately mixing alpha emitting nuclei with beryllium, one produces a source of neutrons. These are known as alpha neutron sources and are the most common neutron source.

The neutron production rate and energies are thus governed by the mixture composition, and the decay rate and energy release of the alpha emitter. To ensure intimate contact, powdered beryllium metal is mixed with an oxide of the alpha emitter, compressed, and doubly encapsulated in a Type 304 stainless steel cylinder. Typical alpha activities ranging from 10 mCi to 40 Ci have been deployed for neutron sources. The alpha emitters most often chosen are either americium-241, plutonium-238, plutonium-239, polonium-210, or radium-226, and the resulting neutron sources are familiarly known as “AmBe”, “PuBe”, or “RaBe” sources. Unlike californium-252, the half-lives of these alpha matters are quite long and so the source retains its strength over time.

When lower energy neutrons are needed, americium can be mixed with fluorine or lithium, instead of beryllium, to produce average neutron energies of 1.5 or 0.5 MeV respectively.

Rather than using an alpha particle to produce an (alpha,n) reaction, high energy photons (~ 2 MeV gamma rays) can also be used. These types of neutron emitters are known as photoneutron sources, and typically use either deuterium (hydrogen-2) or beryllium (beryllium-9) as the target nucleus for the gamma ray. The incident gamma rays come from the radioactive decay of a high activity source, such as antimony-124 (half-life of 60 days). Because the gamma ray has a distinct energy, the neutrons are also produced at a fixed energy. By choosing different gamma ray emitters, different energy neutrons can be produced. Unlike the alpha neutron sources, the gamma rays are highly penetrating and can be kept physically separated from a surrounding neutron emitter. These neutron sources are generally larger in physical size ($\sim$ several cm³) and must be highly shielded due to the intense gamma rays. Photoneutron sources are useful when lower, fixed energy neutrons are needed, but because of the short half lives and high energy gamma rays involved, are only found in research laboratories.

Both alpha- and photo-neutron sources rely upon the energy provided by a radioactive source, and thus require no external power. On the other hand, they cannot be turned off. By using accelerators to provide the energy for the nuclear reaction, additional reactions become available (cf. Table 4), and the supply of neutrons can be turned off.

The most convenient and portable source of fast neutrons using an accelerator involves firing deuterium ions at either deuterium or tritium atoms. The resulting fusion reactions (known as (d,d) or (d,t) reactions) produce monoenergetic neutrons at ~ 2.5 or 14 MeV. Because of the larger reaction likelihood, the tritium targets typically will produce ~ 10 – 100 times more neutrons, and are the most favored. The target is usually composed of a copper or molybdenum substrate, covered by a metal halide film that incorporates either the deuterium or tritium atoms. The accelerators, which can be run in either pulsed or constant current modes, can be made small and highly portable, and the entire unit is commonly known as a neutron generator.

The available intensity of fast neutrons using commercial sealed-tube neutron generators is typically limited to 10^{10-11} n/s. More intense fast neutron sources that use the DT reaction are being developed with significantly higher intensity, but are much larger ($\sim$ a few m³) and expensive (Transforming Nuclear Technology, Phoenix Inc, n.d.). For R&D requiring even more intense sources of neutrons, spallation neutron sources have been deployed over the past few decades. These building-sized facilities use intense accelerators to drive protons (typically $\sim$ GeV) into heavy targets like lead, mercury, or tungsten. The accelerator type may be linear, or a circular variety, such as a synchrotron or cyclotron. When a high energy proton interacts with neutron-rich heavy nuclei, ~ 20 – 30

Table 4 Typical values for alpha- and photo-neutron sources.

Source	Neutron production rate ($\times 10^6$ n/s-Ci)	Average neutron energy (in MeV)	Neutron dose rate at 1 m/Ci (in mrem/h)	Gamma dose rate at 1 m/Ci (in mrem/h)
AmBe	2.2	4.2	2.5	2.5
PuBe	1.7	4.6	2	0.1
RaBe	15	3.6	—	High
Sb-Be	0.2	0.024	0.2	1000

neutrons are produced. These high energy neutrons are typically moderated to lower energies and used as the source for sophisticated neutron measurement stations. Because of the size, sophistication, and cost of these sources, these are typically international user facilities supported by national governments. A current list of 10 well-known global spallation sources is maintained by IAEA (IAEA, n.d.).

While the spallation neutron sources serve as our brightest source of neutrons, the equivalent international accelerator facilities for producing ionizing photons are known as synchrotron light sources or free-electron lasers. The photons are generated when high energy ($\sim$ GeV) electrons are bent by magnetic fields, and the emitted photon energies typically lie in the X-ray energy range of the electromagnetic spectrum. These also tend to be large scale user facilities particularly useful in materials science research. A list of global intense X-ray sources is maintained at [Light sources of the World \(n.d.\)](#).

Introduction

Radiation is the flux of microscopic particles or electromagnetic waves. In nuclear science, microscopic particles mainly refer to charged particles such as alpha particles, electrons, and heavy ions as well as neutral particles such as neutrons and neutrinos. X-rays and gamma rays are electromagnetic waves with energy in the range of keV to MeV and are treated as particles. Most radiations are the products of radioactive decay (Previtali, 2021). To characterize radiation, we study its energy deposition intensity, frequency, timing profile, etc., by measurement devices designed and constructed for this purpose, which we call radiation detectors. Particles interacting with the active medium in radiation detectors lose energy via complicated physical processes, including ionization and excitation.

Radiation detectors, or detectors for short, can be classified by the absorbing medium. Commonly used detector mediums include scintillators, gases, semiconductors, etc. Detectors can also be grouped by the type of radiation detected. For example, an alpha detector measures the number and energy of incident alpha particles—the nuclei of helium atoms. In this chapter, we focus on the detecting principles and characteristics of the three types of most widely used detectors. We will also briefly discuss detectors by the radiation types and auxiliary systems for detectors.

Physics of radiation detection

Radiation is detected via interactions with the detector medium. The interacting mechanism of charged particles and neutral particles in a detector varies significantly. Charged particles ionize and excite the atoms and/or molecules of the detector medium. Depending on the detector type, ionization and excitation signals may be measured either directly or indirectly. For example, excited molecules may return to the ground state by emitting visible light, which can be measured. Neutral particles can be detected only through the secondary charged particles generated when the neutral particles interact with the detector medium.

The physical process of radiation detection is also energy dependent. Possible interactions of gamma rays with the medium are the photoelectric effect, Compton scattering, and pair production. Depending on the incident gamma ray energy, one of the interactions may dominate the energy loss process. We discuss the energy dependence in the following subsections in more detail. A more extensive discussion can be found in Knoll (2010) and Leo (1994).

Energy loss in a medium: Charged particles

Common charged particles include alpha particles, beta particles (i.e., electrons), protons, heavy ions, etc. When a charged particle travels in a detector medium, it loses energy by ionizing and exciting the medium via electromagnetic interactions. In the ionization process, the incident particle knocks out one or more electrons from a target atom. Under the possible influence of an external electric field, electrons and ions may reach readout electrodes and send signals to detectors. In excitation, the incident particle pumps atoms or molecules to excited states, and photons are released in the subsequent de-excitation. Photons can then be collected by photosensors as a measure of the energy deposition of the incident particles.

The energy loss by ionization and excitation per unit travel distance dE/dx is proportional to the atomic number Z and inversely proportional to the atomic mass of the medium. dE/dx is also a function of the velocity of the incident particle. In nuclear physics, the unit commonly used for dE/dx is $\text{MeV}/(\text{g}/\text{cm}^2)$, where MeV is the unit of energy and g/cm^2 denotes the surface density of the medium. With this unit, dE/dx is largely independent of the physical properties of the medium. The energy loss does not vary monotonically with the incident energy. If we take the electron in silicon as an example (shown in Fig. 1), the energy loss dE/dx decreases as the energy increases from keV to approximately 1 MeV. Above 1 MeV, the energy loss has an additional contribution from radiation and increases with incident energy. For the energy around 1 MeV, the energy loss is relatively flat at approximately $0.2 \text{ MeV}/(\text{g}/\text{cm}^2)$.

Energy loss in a medium: X-rays and gamma rays

X-rays and gamma rays lose energy in a medium in three different ways: the photoelectric effect, Compton scattering, and electron-positron pair production. These three effects, respectively, dominate the energy loss when incident photons are in the low energy range (less than 100 keV), medium energy range (approximately 1 MeV), and high energy range (much higher than 1 MeV). Fig. 2 shows the total cross section of photon in germanium, which refers to the probability of photon interacting with the medium as a function of incident energy.

Photoelectric effect: the energy of a photon is fully absorbed by an electron in an atom, and the electron escapes from the atom or even the medium. This photon absorption and electron emission process was termed as the “photoelectric effect.” When an electron in the inner shell of an atom gets knocked out by a photon, the vacancy in the inner shell is filled by an electron from an outer shell. In this process, additional energy is carried away by an X-ray or another electron in the atom (called an Auger electron). The cross section of the photoelectric effect is proportional to the atomic number Z to the fifth power (Z^5).

Compton scattering: the incident photon scatters off one of the electrons in the target atom and transfers part of its energy to the electron. The energy of the outgoing photon is a function of the scattering angle θ , electron mass E_e and incident photon energy E_γ : $E_{\gamma'} = \frac{E_\gamma}{1 + E_\gamma/E_e(1 - \cos\theta)}$. The energy loss $\Delta E = E_\gamma - E_{\gamma'}$ increases with the scattering angle and reaches a maximum value when $\theta = \pi$,

Fig. 1 Energy loss per unit travel distance in silicon as a function of incident electron energy. Data from NIST ESTAR database: <https://physics.nist.gov/PhysRefData/Star/Text/ESTAR.html>.

Fig. 2 Cross section of gamma interacting with germanium. The total cross section is dominated by three interaction mechanism at different energy ranges. The mean free path of a 1 MeV gamma ray is approximately 3 cm in germanium. Cross section data from NIST XCOM database: <https://physics.nist.gov/PhysRefData/Xcom/html/xcom1.html>.

that is, the photon is scattered backward by 180 degrees. In the medium, the scattering cross section is proportional to the atomic number Z and roughly inversely proportional to E_γ .

Pair production: above the energy threshold of approximately 1 MeV, an incident photon is converted to an electron-positron pair under the influence of the Coulomb field of the nucleus. The cross section for pair production increases with the photon energy and starts to dominate at energies above 10 MeV.

The total photon cross section is the sum of all three interactions, each dominating at different energy range. Photons are usually scattered by a large angle in Compton scattering and are absorbed when the photoelectric effect or pair production occurs. Accordingly, one cannot define a stopping range for incident photons. Instead, a signature attenuation length is often defined, after which distance the number of photons is reduced to $1/e$, or approximately 37% of the initial number.

Energy loss in a medium: Neutrons

Neutrons lose energy in a detector medium by nuclear interaction or elastic scattering off a nucleus. We usually classify neutrons into slow neutrons (energy lower than 0.5 eV) and fast neutrons (> 0.5 eV). Slow neutrons are absorbed by nuclear interactions, for example, $^{10}\text{B} + n \rightarrow ^7\text{Li} + \alpha$. The resulting charged particles, an alpha and a ^7Li nucleus in this example, are then detected. A fast neutron transfers energy to the medium more likely by elastic and inelastic scattering off the nuclei. As its energy decreases, the cross section for neutron absorption increases, increasing the probability that the neutron will be absorbed, as shown in Fig. 3.

Fig. 3 Cross section of neutron capture in different isotopes. The commonly used detector material ^{10}B and ^6Li have larger cross section compared with Au. Data from IAEA Neutron cross section standards database: <https://www-nds.iaea.org/standards/>.

Counting statistics and energy resolution

Energy loss in a medium is a stochastic process. The number of quanta, a term sometimes used to refer to the unit energy carrier, including scintillation photons, ionization electrons, and vibrational excitations (phonons), created in a detection process, is subject to statistical fluctuation. The average energy required to create one quantum is denoted as w and differs significantly for different types of detectors. For example, the w value for a silicon semiconductor detector at room temperature is approximately 3.6 eV. Therefore, the average number of electron-hole pairs $\bar{n}$ created in a silicon detector by a 1 keV X-ray is approximately 280. However, the measured number n does not exactly equal $\bar{n}$ but follows a Poisson distribution with a mean value of $\bar{n}$.

The statistical fluctuation imposes an intrinsic limitation of the performance that can be achieved by any type of detector. For a monoenergetic energy input E , the full width at half maximum (FWHM) in the measured spectrum is used to characterize the detector performance and is called the energy resolution. The relative energy resolution, FWHM/E , is widely used as well and is often quoted as a percentage. Broadening of the energy peak due to the statistical fluctuation of n is intrinsic and determines the ultimate resolution achievable by certain types of detectors. For a large $\bar{n}$, the Poisson distribution approaches a Gaussian distribution, and the FWHM is proportional to 2.35σ , where $\sigma = \sqrt{\bar{n}}$ is the standard deviation of the Gaussian function. The relative energy resolution is therefore proportional to $1/\sqrt{\bar{n}}$. To achieve a better resolution, a larger $\bar{n}$ or equivalently a smaller w is desirable.

In reality, the statistical fluctuation is even more complicated. The creation of quanta in detectors is not fully independent; therefore, the observed variance differs from the predicted variance from the Poisson distribution. The ratio between the two is called the Fano factor F (Fano, 1947), and the relative energy resolution is proportional to $\sqrt{F/\bar{n}}$. Clearly, a smaller Fano factor is preferred to have a better energy resolution.

Scintillation detectors

Scintillation detectors are widely used for radiation detection in nuclear science, particle physics, medicinal imaging, homeland security, etc. They are versatile, fast, robust, and relatively low cost. The detector consists of two main parts: a scintillator and a photosensor. Scintillators are the target medium and emit light when radiation interacts with it (shown in Fig. 4). The target can be solid, liquid, or gas. The output light, mostly ranging from ultraviolet to infrared light, is then converted to electrons in the photosensors. The so-called photoelectrons are often multiplied and then converted to electric signals to be processed by electronics and computers.

Principles

The scintillator absorbs radiation and emits light. Incident particles excite scintillator molecules, and the subsequent energy release is in the form of photons in the de-excitation process. To work with photosensors, scintillating materials that emit photons in the visible light range are most widely used. With the development of novel photosensors, scintillation light from ultraviolet to infrared have become detectable with high efficiency, triggering new applications of scintillators.

To maximize the performance of scintillation detectors, the following aspects of the detection process contribute to the signal-to-noise ratio.

1. Light yield defined as the number of scintillation photons per unit energy deposition. The light yield depends on the properties of the scintillator, the incident radiation type, and the incident energy.

Fig. 4 A typical scintillation detector setup with a photomultiplier (PMT). Image courtesy: Hamamatsu (PHOTOMULTIPLIER TUBES Basics and Applications FOURTH EDITION).

2. Transparency of the emitted light in the scintillator. An ideal scintillator would have little overlap between the emission spectrum and absorption spectrum. Accordingly, the majority of emitted photons would reach the boundary of the scintillator, where the photosensors would collect them.
3. Collection efficiency of photosensors. This factor depends on the overall coverage and the quantum efficiency (QE) of the photosensors. Often, photosensors cannot cover the full surface area of the scintillator due to design and/or cost concerns. For example, a cylindrical NaI crystal is nominally coupled to a photosensor on one end, while all the other surfaces are covered with light reflectors. Light reaching the reflectors would be bounced back and inevitably lose its intensity before eventually reaching the photosensor. The photosensor's quantum efficiency, defined as the probability of converting one photon to an electron, is also directly coupled to the overall collection efficiency.
4. Photosensor multiplication gain. To achieve a sizable electric signal, the photosensors multiply the number of photoelectrons by factors from thousands to millions. The multiplication is achieved by either secondary emission in photo-dynode materials of a traditional photomultiplier tube or avalanches in semiconductors, as described later.

Other characteristics, such as the timing profile of light emission, should also be considered when selecting a scintillation detector.

Scintillators

Scintillators, in the form of solids, liquids, or gases, are normally categorized as either inorganic or organic. Inorganic scintillators, traditionally referred to as solid scintillators, usually have higher density and a larger atomic number Z , which means that they are effective in detecting both charged and neutral particles with relatively high energy resolution. However, the decay time of light emission is usually long (at the microsecond level), and the cost is relatively high. Note that noble gases, such as argon and xenon, are excellent scintillators with light emission spectrum in the UV region and light yields comparable to common benchmark scintillators. Noble gas scintillators are gaining more attention in fundamental research and applications (Aprile et al., 2006).

The most widely used inorganic scintillator type is alkali halides, including NaI and CsI. These compounds are often doped with trace amounts of activator to reduce the average energy required to emit a photon and thus improve the light yield. For example, thallium-activated NaI has a high light yield of approximately 40,000 photons per MeV. The emission spectrum peaks at 410 nm and can be easily measured by photosensors. Therefore, NaI(Tl) is often cited as the benchmark scintillator material for comparison with others.

Lanthanide halides are a relatively new family of inorganic scintillators that have very bright output and excellent energy resolutions. Among them, lanthanum bromide (LaBr_3) doped with cerium emits approximately 60 thousand photons per MeV and has good light yield proportionality. The best energy resolution can be as small as 2.8% FWHM at the 662 keV gamma line and is better than that of any other scintillator. For comparison, the typical resolution achieved with NaI(Tl) is approximately 5%. However, the crystals are still quite costly and limited in size when compared with NaI. Other types of inorganic scintillators include alkali-Earth halides, transition metal scintillators, post-transition metal scintillators, rare-Earth oxyorthosilicates, ceramic and glass scintillators, etc. (McGregor, 2018).

Organic scintillators are sold by commercial companies as a cocktail of two or three components in plastic or liquid form (see Fig. 5, for example). The scintillating component is a mixed with a solvent, mainly used as a stabilizer. For example, the KamLAND neutrino detector is equipped with a kiloton of commercial liquid scintillator with two main components: pseudocumene and normal dodecane (Suekane et al., 2004). The former is the scintillator, and the latter is a stabilizing agent used to improve the light

Fig. 5 A wide range of organic scintillators offered by Eljen Technology. Image courtesy: Eljen Technology; <https://eljentechnology.com/products/plastic-scintillators>.

transparency and stability. A third component might be added as a wavelength shifter to shift the emission spectrum of the scintillating component to a range more easily detected by photosensors.

Doping organic scintillators with trace amounts of impurities without significantly impacting the light-emitting performance is also relatively easy to accomplish. A sample to be measured can be mixed in the scintillator (liquid scintillator for practical reasons) for a high-efficiency measurement. Additionally, a special target material, for example, ^6Li with a large neutron absorption cross section, can be mixed in a scintillator to measure a specific radiation.

Photomultipliers and modern photosensors

Photomultipliers (PMTs) are workhorse photosensors that measure the amount of light output from scintillators. A PMT consists of a photocathode, multiple stages of dynodes, and an anode, all of which are packaged in a vacuum tube (see Fig. 6 for illustration). Photons enter the PMT via a front window, usually made of glass or quartz for different light ranges. Electrons are ejected through the photoelectric effect in the photocathodes coated inside the window. The quantum efficiency depends on the material of the photocathode and the wavelength of the incident photons. Under the influence of an electric field, an electron is accelerated to hit the first dynode and knock out multiple secondary electrons. The same process is repeated in later dynode stages, and the final number of electrons reaching the anodes can be 1 million or more. This large number of electrons will trigger a substantial electric signal to be read out by the electronics. The essential characteristics of PMTs are the sensitivity area, response spectrum, QE, and electron gain.

Silicon photomultipliers (SiPMs) are gaining popularity as a new generation of photosensors. The active areas of SiPMs are fabricated via standard lithographic techniques with silicon wafers. A SiPM has an area typically on the mm^2 to cm^2 scale and consists of millions of photodiodes, each of which has sides of a few tens to a few hundreds of microns. The photodiodes are biased in the avalanche mode and give a signal when a single photon triggers the avalanche. In the nominal working mode, not more than one single photon hits one photodiode, and thus, the number of photons can be counted by the number of triggered diodes. Similar to the QE concept for PMTs, a photon detection efficiency (PDE) exists for SiPMs, indicating the possibility of an incoming photon triggering the avalanche. Typical PDE can be comparable to or larger than the QE of PMTs. SiPMs can be sensitive to light from the UV to near-infrared range. The SiPM has a few clear advantages over the PMT. It is more compact in size, not susceptible to the influences of an external magnetic field, and operates with biases smaller than 100 V. Currently the cost per unit area is still higher than that of PMT, but is expected to decrease with wider usage and larger demand.

Gaseous detectors

Working modes

As in the general case, radiation loses energy in a gaseous detector medium by ionizing the gas molecules. A bias voltage is usually applied to the medium and is able to pull the electrons and ions in opposite directions. Although the charges from ions can be read out, a gaseous detector measures the electrons much more often. When drifting along the electric field lines, electrons may recombine with ions, become attached or absorbed by other molecules, and diffuse along transverse directions. Gaseous detectors are designed to carefully compensate for these negative effects and measure the energy, momentum, and trajectory of incident radiation or simply count the number of incident particles.

Gas mixtures of one type of noble gas and a quencher gas are most widely used in gaseous detectors. One example is argon gas mixed with 5% isobutane (C_4H_{10}). The W values, average energy required to create an electron-ion pair, are 26 and 23 eV, respectively, for the two gases. Therefore, the quencher gas decreases the W value of the mixture and reduces the Fano factor. More importantly, the quencher gas suppresses violent avalanches and improves the stability of operation, hence its name (Knoll, 2010).

Different effects dominate the charge collection process for different bias voltage ranges, which are often called operation regions, as illustrated in Fig. 7. At very small or no bias voltage, the recombination of electrons and ions plays a major role. As the bias increases, electrons more effectively drift away from the ionization site and are collected by the anode. This range is usually called the ionization region. With a higher drift voltage, electrons may be accelerated enough to trigger secondary ionization, where more electron-ion pairs are created and in turn may trigger more ionization. This cascade ionization is called an avalanche. Under a certain bias range, the total number of collected electrons, although perhaps orders of magnitude more than the number of primary electrons, is proportional to the initial energy deposition, and thus, the region is named the proportion region. When operated in ionization or proportional regions, the measured number of electrons is proportional to the energy deposition and thus useful for energy measurement. The proportionality can be maintained up to a certain bias voltage, above which the avalanche saturates and the total number of collected electrons no longer reflects energy deposition. This region is called the Geiger-Mueller region, named after the two scientists who discovered it.

The following three types of gaseous detectors are operated in the latter three regions and are the foundations of more complicated detectors.

Ionization chambers

Ionization chambers are operated in the ionization region. The geometry of the electric field in the chambers is often rectangular or cylindrical. A rectangular electric field is sandwiched between a pair of plate electrodes, and a cylindrical electric field has electrodes on the side and axis. Since no avalanche and thus no multiplication of ionized electrons occurs, the ionization chamber is more suitable for counting the number rather than measuring the energies of individual incident particles. It is also widely used for measuring heavy particles with high energy (MeV or higher). One application is to measure fission fragments from uranium or thorium. On the other hand, because the number of electron-ion pairs is not sensitive to the bias voltage, ionization chambers are robust and low-maintenance. A household smoke detector is an ionization chamber with open air as the gas medium and two plate electrodes biased by batteries. Alpha particles from an ^{241}Am source ionize the air continuously, and a stable signal exists in the smoke detector. In the case of excessive smoke in the ambient air and thus in between the electrodes, ionized electrons are absorbed by smoke particulates, and the electric signal is interrupted, triggering an alarm.

Proportional chambers

Proportional chambers can count the number and measure the energies of incident particles. The electric field is nominally 10 kV/cm or higher to reach the proportional region. Cylindrical chambers are often used to reach this high electric field around the electrode along the axis. With their high gain, proportional chambers are often used to measure neutrons, electrons, and X-rays. Proportional tubes with BF_3 or ^3He are widely used for neutron measurement.

Geiger-Mueller counters

Handheld Geiger-Mueller counters are ubiquitous equipment to measure the radiation level in an ambient environment (Fig. 8). Cylindrical tubes with electrodes biased at the Geiger-Mueller region are sensitive to very low levels of alpha, beta and gamma radiation. Due to its high multiplication factor, the large pulsed signal can be read out by straightforward, inexpensive, and robust

Fig. 7 Illustration of operation regions of gaseous detectors.

Fig. 8 A handheld Geiger-Mueller counter commonly seen in research labs. Public domain image. https://en.wikipedia.org/wiki/Geiger_counter#/media/File:Geiger_counter_2.jpg.

electric circuits. Furthermore, the gas tube itself is also of low cost and robust compared to other radiation counters (semiconductors, for example). However, the Geiger-Mueller counter cannot measure energy or identify radiation types.

Position-sensitive detectors with wire readouts

More complicated gaseous detectors have been developed to measure the energies and trajectories of incident particles. Instead of a single readout channel as in the basic types, these new types of gaseous detectors with high spatial granularity may have hundreds, thousands, or even more anode channels between two parallel cathode plates. Multiwire proportional chambers (MWPCs), as the name suggests, have multiple anode wires in the setup, each one serving as an independent proportional chamber (Charpak et al., 1968). The wires are usually equally spaced, and each wire is sensitive to the nearby space. Once an incident particle travels inside the chamber and deposits energy along the way, the corresponding wires register the signals. With two groups of anode wires in orthogonal directions, the trajectory's projection in the detector plane can be determined.

The time projection chamber (TPC) further develops the concept of the MWPC to achieve a three-dimensional spatial resolution (Nygren, 1974). The TPC enlarges the gap between the anode wires and cathode to obtain a dedicated drift region. Ionized electrons in the region drift to the anode wires, and the travel time multiplied by the electron drift velocity gives the position along the drift direction, i.e., normal to the anode plane. TPC detectors are widely used in nuclear and particle physics experiments. Fig. 9 shows a large TPC from the STAR experiment at Brookhaven National Laboratory during the construction phase.

With the rapid development of lithography technology, microstructured readout planes are becoming a viable substitute for the traditional anode wire planes. The micromesh-gaseous structure (MICROMEGAS) (Giomataris et al., 1996) and gas electron multiplier (GEM) (Sauli, 1997) are two successful electron multiplication and readout schemes.

Semiconductor detectors

Semiconductor detectors have revolutionized radiation detection technology since they were first introduced approximately 60 years ago. Similar to gaseous detectors, semiconductor detectors measure the electron-ion pairs created by incident radiation. Commonly used semiconductors include silicon, germanium, and compounds such as CdTe and GaAs. The W value for Si is 3.6 eV at room temperature and slightly higher at lower temperatures. Germanium semiconductors, usually operating in a cryostat, have a W value of 3.0 eV at liquid nitrogen temperature. The W value in semiconductors is approximately an order of magnitude smaller than that in gas; thus, the number of electron-ion pairs created per unit energy deposition is much higher. The resulting energy resolution of semiconductor detectors is far superior to almost all other technologies.

In semiconductors, electric charge can be transported by either electrons or holes. When electrons are the dominant charge carriers, the semiconductor is called N-type. Otherwise, it is called P-type. Intrinsic P-type (N-type) semiconductors can be doped with implants to provide additional free electrons (holes) and reverse their type. With implantation, P-type and N-type materials can be joined together to form P-N junctions. When the N-type end is biased positively and the P-type end negatively, a large depletion region is formed in the P-N junction, where no free moving charge carriers exist. The sensitive volume of a semiconductor detector is the depletion region. With reversed biasing, the insensitive volume is thin, and the depletion region can occupy the vast majority of the detector volume. When an incident particle ionizes the detector and creates electron-hole pairs, it travels to the electrodes under biasing and creates a pulsed signal. Similar to gaseous detectors, charge carriers may also become trapped while drifting. To maintain good proportionality between energy deposition and pulse amplitude, the so-called lifetime of charge carriers should be much higher than the drift time. The lifetime depends on the crystal quality, purity, and fabrication of the semiconductor is key to good energy resolution.

Silicon detectors

Monolithic silicon detectors have been widely used to measure the energy of proton, alpha, heavy ion, and X-ray radiation. Aided by the ever-evolving silicon-based integrated circuit industry, strip or pixel silicon detectors are maturing and can measure the tracks of incident particles with high granularity.

The monolithic P-N-junction-type silicon detectors have good energy resolution and fast response to the energy loss of alpha and other charged particles. For 5.486-MeV alphas from ^{241}Am , the energy resolution (FWHM) is less than 10 keV. The electrodes can be fabricated via coating, thermal diffusion, and ion implantation. The surface areas of these alpha detectors can be as large as 3000 mm², but the thickness is limited to approximately 2 mm. Therefore, silicon detectors are suitable to measure the energy loss of alpha particles or charged particles but not high-energy gamma rays. When measuring penetrating particles, the thickness uniformity of the detector is also an important specification. Silicon detectors with drifted lithium, usually called Si(Li) detectors, create an intrinsic layer inside the P-N junctions. Si(Li) can be larger in volume and are used for X-ray detection.

Highly segmented silicon detectors such as silicon microstrip detectors and charge-coupled devices (CCDs) may have thousands or even millions of strip and/or pixelized channels. Each channel is a miniature P-N junction to measure the timing and energy information of passing radiation. Together, the detectors measure one- or two-dimensional spatial information with high granularity. Development of those tracking detectors has benefited from the integrated circuit industry. Currently, the possibility of integrating detection and front-end electronics on a single silicon wafer is being actively pursued.

Germanium detectors

Germanium detectors must be operated at low temperature, usually being cooled by liquid nitrogen (77 K) dewars. Compared with silicon semiconductors, the band gap of germanium semiconductors is so small that the leakage current due to thermal fluctuation at room temperature is too large to ignore. Germanium can be diffused with lithium to form Ge(Li) detectors, but the most common usage is high-purity germanium (HPGe) detectors (Fig. 10).

HPGe detectors are made of large, single germanium crystals with P-N electrodes. The impurity level must be less than the 10¹⁰ atom/cm³ level. The crystals can be larger than a kilogram. By maximizing the detector size while keeping the junction capacity low, HPGe detectors have the best energy resolution of all commonly used radiation detectors. For gamma radiation of a couple of MeV, the energy resolution (FWHM) can be as good as 0.1%. Fig. 11 demonstrates the sharp contrast between the performance of a sample HPGe detector and a NaI scintillation detector. Considering the relatively large atomic number ($Z = 32$) and thus the effective absorption of high-energy gamma rays, HPGe detectors are the ideal detector for gamma spectrometry from 0.01 MeV to a few MeV.

An array of germanium detectors can be closely packed together to measure the extremely low intensity of X-rays or gamma rays from rare nuclear interactions or decays. Arrays such as GAMMASPHERE (Lee, 1990), AGATA (Akkoyun et al., 2012), and GREINA (Fallon et al., 2016) are packed into spherical configurations to maximize the detection efficiency of events originating from the spherical center. One single HPGe crystal can also be segmented to make multiple detectors, with the objective of better position resolution.

Fig. 11 Comparison of energy resolution from a sample HPGe semiconductor detector and a NaI scintillation detector.

Compound semiconductor detectors

Compound semiconductors such as CdTe, CdZnTe, and GaAs can be fabricated into room-temperature detectors to detect X-rays, gamma rays, and neutrons. The energy resolution is not as good as that of germanium detectors, but the operation at room temperature is a huge benefit. For this reason, compound semiconductor detectors are gaining popularity in the X-ray screening and medical imaging industries.

Specialty detectors

Specialty detectors, such as bolometers, bubble chambers, and emulsion-tracking detectors utilize special features of a detector medium. For example, bolometers measure the incident energy via the temperature change of the detecting medium itself. To have a measurable temperature rise with input energy levels in nuclear decays (MeV range), the detector has to be cooled to sub-Kelvin temperature to significantly reduce the heat capacity. The cryogenic requirement limits its application to research labs.

It is worth noting that the ubiquitous radiation monitoring badges use emulsion-etching detection techniques. Emulsion detectors consist of ionization-sensitive silver halide grains embedded in gelatin films. Incoming radiation sensitizes the grains and causes silver atoms cluster on the surface of grains. Once developed, the sensitized grains appear visibly darken and are good indicators of the flux of radiation. To enhance the dynamic range of radiation detection, a radiation monitoring badge may have emulsion films of different sensitivity, or with different types filters in front of the films. An emulsion-tracking detector differs from previously mentioned detectors in one significant way: it is a passive detector with no real-time detection. However, it offers a cheap and maintenance-free method to monitor the accumulated flux of radiation exposed to the badge-wearer.

Applications by radiation type

X-ray and gamma detectors

X-ray energy varies from sub-keV to approximately 100 keV. For the detection of low-energy (soft) X-rays, CCD and CMOS (Complementary Metal Oxide Semiconductor) image sensors are often used. In research labs, bolometers can be used for their good energy resolution and low threshold. For high-energy (hard) X-rays, the detection is not much different from that for gamma rays and is often done by scintillation and semiconductor detectors. Scintillators coupled with silicon PIN (P-Intrinsic-N type semiconductors) diodes, SiPMs, or PMTs are widely used in security and medical imaging applications. Silicon and germanium detectors are more often used for precise measurements of energies and intensities. For example, large (kg-scale) HPGe is essential in measuring ultralow levels of gamma radioactivity with high efficiency and unprecedented energy resolution.

Charged particle detectors

For alpha particles and ions in the sub-MeV and MeV energy range, surface barrier silicon detectors are often used for energy measurement. A silicon detector telescope, sometimes called a ΔE -E detector, measures the partial energy deposition (ΔE) in the first thin detector and the rest of the energy in the second thick detector. Since the energy distribution depends on the charge (Z) and mass (A) of an incident particle, one can identify the charged particle with the detector telescope.

Neutron detectors

Neutrons are usually detected by absorption or elastic scattering. For example, helium-3 can absorb a low-energy neutron with a large cross section and emit a proton and a tritium. The energy release of 764 keV is carried away by the two daughters. A ^3He proportional counter uses helium gas as the working medium and measures the energy of the daughters (Fig. 12). Similarly, ^6Li and ^{10}B are used for neutron absorption measurements. The isotopes can be loaded in scintillators (solid or liquid) or form gaseous compounds (e.g., $^{10}\text{BF}_3$) as the detector medium. To distinguish neutrons from other types of radiation in scintillators, special scintillators are developed to have different pulse shape responses by the radiation type. Fast neutrons can be slowed down with a moderator and then absorbed in a detector. A Bonner sphere, a lithium iodide scintillator wrapped inside a polyethylene shell moderator, can be sensitive to neutrons of different energy by varying its shell thickness. Fast neutrons can also be detected by elastic scattering, especially on light nuclei, such as hydrogen in organic scintillators.

Neutrino detectors

Neutrinos are neutral particles with tiny (but nonzero) masses. They interact extremely weakly with the medium; hence, detectors have to be specifically designed and fabricated to measure neutrinos from the Sun, the Earth, power reactors, neutrino beams, etc. The small interaction probability must be mitigated with an extremely large detection medium volume. While neutrinos can be detected by semiconductor and gas detectors, the cost of a gigantic detector is prohibitive. Among the three types of detectors we described earlier, scintillation detectors are the most widely used technology for neutrino detection. For example, the KamLAND detector in Japan, illustrated in Fig. 13, (Suekane et al., 2004) has 1 kt of liquid scintillator with approximately 2000 PMTs. More recently, liquid noble gas detectors, especially liquid argon TPCs, such as the proposed DUNE detector in the US (Abi et al., 2020), provide excellent tracking capability and energy measurement for 3-dimensional neutrino event reconstruction. All of the aforementioned detectors operate deep underground to minimize cosmic muons' impact.

Neutrino detection is also a promising technology for nuclear safeguards, which include monitoring of known and undisclosed nuclear reactors, spent fuel reprocessing, nuclear explosions, etc. Medium and large-scale detectors underground or near surface are often required for potential applications. For a comprehensive review, please refer to Bernstein et al. (2020).

Auxiliary systems for radiation detection

Electronics are an integrated part of a radiation detection system. The electric signal output from the detection medium, either continuous or pulsed, will be fed into electronics, where it may be amplified, shaped, and digitized. Electronics are designed to extract as much information from the detector output as possible without degrading it. One or more stages of amplification are often necessary when the output electric signal from the detector medium is small, such as in semiconductors. On the other hand, PMT and gaseous detectors may have amplified signals sent directly from the detector; hence, additional amplification in electronics is not necessary. The shape of the output pulses may also be reshaped for timing and amplitude measurements. Many modern detectors are connected to computers and have measured results displayed and stored there. Analog-to-digital conversion is therefore necessary. Traditionally, this conversion is performed on key parameters such as the arrival time and amplitude of pulses. With the rapid development of electronics and computers, whole pulses can be digitized and stored for further data analysis in computers. The conversion can be as fast as billions of sampling points per second.

Vacuum systems, high-voltage systems, and cryogenics are other auxiliary parts commonly seen in radiation detectors. For example, to measure alpha emissions from a sample, the sample is placed facing a silicon surface barrier detector. The setup has to be pumped down to good vacuum to avoid alpha particles being absorbed or slowed down before arriving at the detector. Many detectors, including PMTs, gaseous detectors, and HPGe detectors, require DC high voltages, sometimes as high as a few thousand volts, to provide the electric field potential essential to the operation of detectors. HPGe detectors are a good example for cryogenics, which are often cooled to slightly above liquid nitrogen temperature with a dewar.

Need for accelerators: Applications

Electron and ion accelerators can deliver beams of 10^{13} – 10^{16} particles per second with a very well-defined size ($\leq$ mm), direction ($\approx$ milli-radians), and energy. Although initially conceived to explore subatomic physics, they have become tools used for a wide variety of applications, such as: analysis of radiation damage, important for the aviation industry and neutron reactors, ion implantation for high-density electronics, food and medical instrument sterilization, radioisotope production for medical diagnostics and treatments, accelerator mass spectrometry for highly sensitive radiocarbon dating and geological applications. Accelerators producing proton and carbon beams have been installed at many thousands of hospitals around the world for cancer treatment: taking advantage of the fact that most of the ionization occurs near the end of the trajectory, beams are used to effectively destroy tumors with minimal damage of healthy tissue. Microbeams with sizes of microns or smaller can be used in combination with X-ray detection to produce high-spatial-resolution images of concentration of selected elements in biological, medical, or geological applications. Accelerators are now used as high-flux X-ray sources by undulating positrons and electrons which are used for exploration of condensed matter devices. More examples on applications are given in Bjørnstad (2021).

Ion and electron sources

The first stage in the acceleration process requires extracting the charged particles to produce a beam. For electrons, this is typically done by shining UV light on metals or heating up filaments. For ions of gaseous elements, radio-frequency (RF) discharges are used for ionization. A magnet is used in combination with a filament to generate a plasma, from which the ions are extracted. Fig. 1 shows a typical arrangement. Alternatively, to produce ions from solids, an alkali, like Li, or Cs, is ionized by heating and accelerated toward a cathode made of the wanted element. On collision, the alkali sputters charged ions from the solid. Another very successful type of source, developed in the 1980s, is the Electron Cyclotron Resonance (ECR) source (Lyneis et al., 2010). The basic idea is similar to the gaseous source mentioned above, in that a plasma is made, that allows for ionization. However, the RF works at the electron cyclotron resonance, allowing heating of electrons in the plasma at will. The radius of the ECR source is much larger to allow containing the higher-temperature plasma. The ECR ion source is efficient at producing ions with high charge states, which can be used to increase the acceleration in accelerators. Solids can be sputtered into the source gas allowing production of ions of a wide variety.

The beam properties are characterized by a *beam emittance*, expressed in units of area times solid angle, e.g. mm² steradian. As the beam is shaped with electromagnetic devices it can be focused into waists at certain points at the cost of a larger angular divergence, but conservation laws prevent improving the emittance without losing intensity. In an efficient machine, the emittance is defined at the source, so its design is crucial for efficient delivery.

The challenge in most ion sources is to generate the highest currents in stable fashion while minimizing emittance and maintenance expenses. Electron sources yielding up to several milli-Amperes of current, including the possibility of extracting polarized electrons, have been achieved with GaAs photocathodes. Similar currents can be reached with some ion sources.

Typical power supplies for beam extraction go up to a few tens of kilovolts. The ion or electron sources are placed on an insulated platform that can be brought up to a 100–300 kV potential. For higher energies, several ingenious machines have been invented, of which we will describe a few in what follows.

Fig. 1 Sketch of elements of a typical ion source. The combination of gas at appropriate pressures, a magnet, and a heated filament that eject electrons is used to create a plasma that ionizes the gas. Appropriately shaped electrodes help create an efficient emission pattern in a particular direction creating a beam.

Fig. 2 Sketch of elements of a tandem Van de Graaff accelerator. To prevent sparking, a tank is used as shown to hold the accelerating tube embedded within high-pressure (typically 10 atm) Nitrogen + CO₂, or SF₆. For a 9-MV tandem, for example, the tank diameter and length are about 4 and 30 m, respectively.

Electrostatic accelerators

The first successful accelerator was produced by Cockroft and Walton, who made use of two chains of stacked capacitors. Using switches to move the connecting points between the chains, they were able to generate voltages of approximately 1 MV. Up until 2012, the Fermilab accelerator system made use of Cockroft-Walton accelerators for its initial stages. They were replaced by Radio Frequency Quadrupole cavities, which will be described below.

Van de Graaff accelerators, sketched in Fig. 2, use a belt to move charge from the ground to a high-potential terminal. The basic idea is commonly used in demonstrating units shown in science museums around the world. Van de Graaff accelerators contain a vacuum tube that allows for ions to propagate. This tube consists of a series of insulating and conducting rings, connected by resistors that guarantee a linear variation of the potential along the length of the acceleration tube. Hoops of toroidal shape surrounding the conducting rings, are used to decrease the chance of sparking. The potential can reach up to more than 20 MV. A *tandem* version with a positive high-voltage terminal at the center combined with negative ions is typically used to maximize the energy range of extraction energies. On their way through the vacuum tube, negative ions reach the terminal where they traverse a stripper foil or gas that changes the sign of the ion charge and can multiply it for ions with higher atomic number than hydrogen, thus allowing for a gain in energy at a given terminal voltage. Tandem Van de Graaff accelerators can deliver a wide variety of beams, from hydrogen to gold or heavier, and are very stable and easy to manipulate. In modern versions the charging belt is a special chain called a *pelletron* that improves stability.

Cyclotrons and synchrotrons

The cyclotron, invented by Lawrence, is based on another ingenious idea. Consider a uniform magnetic field, of magnitude B , used to bend ions' orbits into semicircles, as shown in Fig. 3. The ions move inside either of two flat half-cylindrical metallic cavities, called D's because of their shape.

Fig. 3 Sketch of elements of a cyclotron accelerator. A magnetic field (oriented out of the page for negative ions) bends the orbits into semicircles. The potential difference between the two D's is flipped every time the particle is about to cross from one D to the other. Diameters can range from less than a meter to almost 20 m.

Fig. 4 Left: Sketch of elements of a synchrotron accelerator. Particles are ejected after several turns. What is shown as a single C-shaped magnet, is in practice done with several dipole and other magnets. Right: photo showing some of the RF accelerating cavities for the SPS at CERN. From <https://cds.cern.ch/images/CERN-PHOTO-201902-032-1>

A potential difference between the two D's accelerates the ions every time they move from one D to the other. The frequency of these events is twice the cyclotron frequency, f_c , which can be calculated by equating the magnetic force to the centripetal force:

$$f_c = \frac{qB}{2\pi E/c^2} \quad (1)$$

where q is the ion charge, and $E = K + mc^2$ is the ion's total relativistic energy, with K its kinetic energy and m its mass. In the *non-relativistic limit*, in which $\frac{K}{mc^2} \ll 1$, the cyclotron frequency is independent of the ions' kinetic energy. Thus, by flipping the voltages at a constant frequency, the ions are accelerated while going into larger and larger orbits, as shown in Fig. 3. An additional magnet allows ejection of the ions when they reached the outer radius.

Cyclotrons can have diameters from a fraction of a meter up to close to 20 m. Typically, they can deliver higher intensities and energies than tandem Van de Graaf accelerators. For this reason, they have been very successful at producing radionuclides for pharmaceutical applications, as well as for the study of unstable nuclei. There are more than 25 facilities worldwide dedicated to nuclear physics studies using cyclotrons.

In order to accelerate ions beyond the point where $K \ll mc^2$, the synchrotron was invented. It uses a principle similar to that of the cyclotron, synchronizing the times for the accelerating pulses to correctly account for the relativistic effect indicated in Eq. (1). In practice, the idea is implemented in a fashion sketched in Fig. 4. The ions move in a ring magnet with C-shaped cross section, allowing higher radii than would be possible with a magnet covering the whole circular area. The radius of the circle is fixed, but the magnetic field is ramped appropriately with time, to keep the ions in circular motion.

Synchrotrons are used, for example, in the CERN collider to bring protons to up to energies of 450 GeV, as part of their acceleration complex. The diameter of the 450-GeV Super Proton Synchrotron (SPS) is approximately 7 km. The "C-shaped" magnet, which appears as a single unit in the sketch at left in Fig. 4 is actually composed of 1317 magnets, of which 744 are dipole magnets.

Optical elements

In order to adjust the beam optics for efficient transport through the accelerator, several electromagnetic devices are used. Steering and focusing of the beam is typically achieved with dipole and quadrupole magnetic fields, respectively. Electrostatic elements can be used for energies below 1 MeV, but the necessary fields become too large for higher energies. Fig. 5 shows photographs and sketches the forces on a quadrupole. With the configuration shown in the sketch at right for the quadrupole, a beam of positive

Fig. 5 Left: photo of typical magnetic dipole, used for steering, which produces relatively uniform fields in the vertical (horizontal) direction, that steer the beam in the horizontal (vertical) directions. Center: photo of quadrupole, used for focusing. Right: sketch showing the poles of the magnets and magnetic field lines (in black), and the resulting magnetic forces on positive ions moving into the page (in red).

Fig. 6 Sketch of typical magnetic field lines in a cyclotron. The arrows indicate the magnetic force on positive ions. The poles are shaped to produce a vertical restoring force.

ions moving into the page, for example, would get stretched in the vertical direction, and compressed in the horizontal direction. A combination of two or three of these elements is used in sequence with a net result of focusing.

Betatron oscillations and stable orbits

Injected beams have a finite emittance, with the beam momentum having some spread in magnitude and direction. Considering the cyclotron, for example, a completely uniform magnetic field would result in a very low efficiency to accelerate ions. In what follows, one should bear in mind that the field is mainly in the axial (z) direction, with small components in the other directions.

The poles of cyclotrons are actually shaped to yield fields that decrease with increasing radius, as shown in Fig. 6. A quantity called the *field index* is used to characterize this variation:

$$n = - (dB_z/B_z)/(dr/r) \quad (2)$$

where B_z is the field in the axial direction. At a given radius, the field varies roughly as

$$B_z = K/r^n \quad (3)$$

with K a constant. Fields that decrease with r , as those shown in Fig. 6, have positive field index, $n > 0$. Fig. 6 indicates with arrows the direction of the magnetic forces. As can be seen, the arrangement naturally leads to restoring forces in the axial direction. The larger the field index, the larger the restoring force in the axial direction.

A sketch of the magnetic force versus radial position that results from the axial field magnitude variation of Eq. (3) is compared to the force needed to keep ions in a circle (the centripetal force) in Fig. 7. The desired radius for the ion tracks is called r_0 . Consider fields with indexes $n > 1$: an ion that finds its way into an orbit with $r < r_0$ will experience a magnetic force larger than the needed centripetal force and will be dragged toward the center; an ion that finds its way into an orbit with $r > r_0$ will find a magnetic force weaker than needed and will thus move further away. Thus, indexes $n > 1$ lead to unstable orbits. On the other hand, indexes $n < 1$ behave oppositely, leading to forces that tend to restore the radial position. The condition for orbits stable both vertically and horizontally is then $0 < n < 1$. Under these conditions, the ions move oscillating around a closed orbit. These are called *betatron oscillations*. The scheme leading to stable orbits, described above for the cyclotron, is also employed for synchrotrons.

This type of arrangement is called *weak focusing*. The fields in this case are mostly invariant in the main direction of motion, so ions experience small variations of field as they move around. For the higher energy synchrotrons, however, this weak focusing is not enough to prevent large unwanted oscillations of the beam. Fortunately, another mechanism, called *strong focusing*, or *alternating*

Fig. 7 Sketch of possible variations of the magnetic force (continuous blue) in comparison with the needed centripetal force (dashed red) versus radial position. The radial position marked r_0 is the wanted radius for the ion tracks. Left: field indexes $n > 1$ lead to unstable orbits. Right: field indexes $n < 1$ lead to stable orbits. After Livingood JJ (1961) *Principles of Cyclic Particle Accelerators*. Princeton, NJ: D. Van Nostrand Company, Inc.

Fig. 8 Left: Sketch of a drift-tube linear accelerator. Charged particles move in bunches inside of the conducting tubes at constant speed, experiencing electric fields when moving in-between them. The length of the tubes varies to guarantee that particles are always accelerated in the same direction. Right: photo of inside cavity of a linac. From <https://www.isis.stfc.ac.uk/Pages/Inside-the-ISIS-linear-particle-accelerator.aspx>

gradients, was discovered that allowed controlling the large oscillations. It turns out that shaping the fields such as to yield alternation between large positive and negative field index values at suitable azimuthal intervals, yields net focusing forces an order of magnitude stronger than with weak focusing.

Practical cyclotrons and synchrotrons make use of these focusing effects, without which practical devices would be very inefficient. A practical cyclotron has several magnets, breaking the azimuthal symmetry suggested in Fig. 6. Likewise, for synchrotrons. The thousands of magnets indicated for the SPS above are partially for this purpose.

Linear accelerators

Linear accelerators (linacs) are based on a very simple idea, sketched in Fig. 8: oscillating electric fields accelerate bunches of ions during part of the oscillation. Conducting tubes prevent the ions from decelerating during the part of the cycle when the fields point in the unwanted direction. The length of the electrodes is designed according to the velocity of the particles.

Although ideas about linear accelerators existed in the 1930s, the technology for sufficiently intense oscillating fields at the needed frequencies (tens of MHz and higher) became available only after the 1940s, benefiting from the radar developments during World War II. A linac for GeV electrons in continuous-wave operation, as example, needs several tens of klystrons (RF high-voltage amplifiers), each delivering several kilowatts of power at ≈ 1 GHz. In practice, rather than the arrangement suggested on the left of Fig. 8, the tubes are placed within a copper cavity and RF of the proper mode is injected to generate the fields in-between the electrodes, as can be seen on the photo on the right of Fig. 8.

Because it is important to keep the particles grouped in bunches, careful considerations to avoid spreading are used. The shielding tubes can be set up such that particles accelerate only during a fraction of the cycle, when the acceleration is positive and increasing. In this way, particles that are late within the bunch are accelerated by larger fields than early ones, contributing to *phase stability*.

Linacs are the most common type of accelerators today. Applications range from electron linacs used for producing high-intensity radiation for industrial and medical applications, and for basic research in subatomic physics, to heavy ion accelerators used to explore properties of the strong force in relativistic heavy ion collisions. Fig. 9 shows a schematic diagram of the Facility for Rare Isotope Beams, planned to start operations in 2022 at Michigan State University. The facility will produce radioactive nuclei via a 400-kW superconducting linac to produce the primary reactions and then extract secondary beams to study nuclei far from stability.

For particles travelling at speeds near the speed of light, linacs can use travelling waves, synchronizing waves of electric field to accelerate the particle bunch, in a way similar as used by surfers at the beach. Interestingly, the phase velocity (e.g., the velocity at which a wave crest travels) for waves in RF guides is larger than the speed of light, so irises are used to slow down the electromagnetic wave phase speed to accompany the particle bunch.

Fig. 9 Example of a linear accelerator used for exploring nuclei far from stability. This is a schematic drawing of the Facility for Rare Isotope Beams (FRIB) at Michigan State University, which will enable scientists to make discoveries about the properties of rare isotopes, nuclear astrophysics, fundamental interactions, and applications for society, including in medicine, homeland security, and industry. Credit: Michigan State University.

Fig. 10 Sketch of electrodes profile in a RFQ accelerator.

In order to achieve high fields minimizing dissipation, superconducting cavities are used. Many of the modern linacs are superconducting, but this increases the cost significantly. Remarkably, an accelerator under consideration for the future, called CLIC, is being designed to reach electron and positron beams up to 3 TeV, without the use of superconducting cavities.

Linear accelerators of the type described above are not well suited to accelerate ions directly from an ion source. Ions are typically pre-accelerated by *injectors* that bring ions to within $\approx 10\%$ of the speed of light. An alternative type of linear accelerator that has become popular for low-energy applications, or for injectors to the linacs described above, is the Radio Frequency Quadrupole (RFQ) accelerator. At a given time, the electric fields in the RFQ look similar to the magnetic fields shown in Fig. 5. In the RFQ, however, the fields are made to oscillate in time, and the poles profiles vary versus the axial position, as shown in Fig. 10. This modulation in the profile generates net longitudinal accelerations. As indicated above, the initial stages of proton acceleration at Fermilab, for example, have been replaced by RFQs. RFQs are also used for reaccelerating the secondary beams at the FRIB facility shown in Fig. 9.

Colliding beams, the energy and intensity frontiers

The quest for reaching higher beam energies and intensities, driven by the desire to study the frontiers of physics, has been the driving force for the development of accelerators.

As example of the high-energy frontier, the LEP (Large Electron-Positron) collider at CERN was very successful as a tool for physics discovery. What matters for discovery is the collision energy in the center of mass (COM), so two beams are made to collide

at special locations, surrounded by efficient detection systems. Compared to a fixed-target experiment, the energy can be doubled using the same accelerator system, but now the two beams need to be exquisitely controlled such as to yield the appropriate luminosity. The beams are focused as much as possible at the collision points. An important development that allowed the highest luminosities, was the development of *stochastic cooling* of the beams, using information on the transverse velocities to make corrections and improve emittances. The LEP collider achieved energies of up to 209 GeV and luminosity of $10^{32} \text{ cm}^{-2} \text{ s}^{-1}$ before it was shut down in the year 2000. It allowed for high-quality data about the Z and W bosons building great confidence in our theory for how nature works at its fundamental level through many studies. The LHC (Large Hadron Collider) is a machine built for proton-proton collisions at energies of 7–14 TeV in the COM. It has already made an important discovery in finding the Higgs boson while running at 7 TeV, which was announced in 2012. In 2016 the LHC started running at 13 TeV. The LHC collider is part of the accelerator complex at CERN, located underground in a tunnel of approximately 27 km in diameter.

A future electron-positron collider that could reach beyond 250 GeV (energies well below those of the LHC) could allow for searches for new physics with much higher sensitivity than achieved with the LHC. This is so due to the higher backgrounds generated in the proton-proton collisions. Two concepts are being developed, the International Linear Collider (ILC) and the Compact Linear Collider (CLIC). The main challenges for both concepts are yielding reliable and power-efficient acceleration (demanding RF technology developments) and achieving 100 times larger luminosity than LEP (demanding beam optics developments). The Future Circular Collider (FCC) would be similar to the LHC but bigger and reaching approximately 10 times its energy. These machines are expensive and require large international collaborations. However, the resolution of existing mysteries and the possibility of new findings at the physics frontier provide strong motivation.

As example of the intensity frontier, the electron-ion collider, a system of linacs to allow understanding of QCD, our theory of the strong force will be built at Brookhaven National Laboratory (Accardi et al., 2016).

155

The predominant use of nuclear energy today is in the generation of electricity for consumption by the world's electricity markets. While there have been some other uses that could be considered commercial, such as transportation or district heating, these instances have, to date, been extremely limited. This article provides the reader with a perspective on the world's 441 presently capable of operating (as of 2020) nuclear power plants, have the ability to generate some 393 Giga-Watts ($\text{GW} = 10^9 \text{ W}$) of electricity. That's approximately 10% of the world's electricity generation.

A brief historical perspective on the development of the technology that became the commercial nuclear power industry is given in the first chapter, "History of the Development of Nuclear Reactors" (Maldonado and Brown, 2021). This article covers the rapid advancement of the technology that was essentially originally geared towards military propulsion and then harvested to provide terrestrially based electricity generation, starting with the first light bulb lit in Arco, Idaho, and progressing to today's carbon-free gigawatt class power plants.

In the article "Physics of the Fission Chain Reaction in Thermal and Fast Reactors" (Tsvetkov and Stachowski, 2021), an introduction to the underlying physics of the nuclear chain reaction, and its control, is provided. Entire tomes are written that discuss various facets of these principles, so the material presented is structure to be accessible to those who do not have a nuclear engineering background, but are nonetheless familiar with basic physics and mathematical techniques of equation solving. A discussion of nuclear reactions, those resulting in nuclear fission, absorption and scattering, as well as nuclear radiation is provided, in order for coverage of reactor physics principles of moderation and reactivity to be understood. This article further introduces the concepts of neutron flux and its behavior in finite systems, in both thermal and fast neutron spectrum type reactors.

These governing concepts are expanded upon to introduce the basic design principles that underpin the engineering foundation of a nuclear reactor in the article "Principles of Design and Operation of Nuclear Power Reactors" (Hamon, 2021a). While there are numerous styles of reactor, which are based on different thermal-to-electrical energy conversion cycles as well as mechanisms of moderation, steam generation and reactivity (chain-reaction) control, the safety and design requirements are, at a high level, the same among reactors. Over the years, a relatively consistent set of standards, for both design and for licensing have been put into place. These standards cover everything from environmental assessments and grid interface to redundancy and diversity in control and safety systems.

The next six chapters each cover reactor types of different technological bases. The first of these, "Pressurized Water Reactors" (Brown, 2021), cover the reactor type (PWR) that comprises the largest portion of the commercial nuclear fleet. While there are several different styles of these reactors, these all share the principle of being moderated and cooled with non-voided (non-boiling) light water (i.e., H_2O) in a primary loop, with a secondary loop responsible for steam generation to feed the turbine-generator set. The chapter covers key equipment, such as the reactor pressure vessel, steam generators, fuel assemblies, emergency core cooling systems and the control systems, which use both dissolved boron in the coolant as well as a discrete control rod insertion system for shut down capability. The function and major design considerations of each component is discussed and illustrated with schematic type figures.

The next chapter deals with the type of reactor whose steam generation occurs directly in the core. In "Boiling Water Reactors" (Hamon, 2021b), the key systems of the BWR are discussed, including the channeled fuel assemblies, control rod system, steam separators, steam dryers, coolant recirculation system and emergency core cooling systems. The function and major design considerations of key components are discussed and illustrated with schematic type figures.

"Heavy Water Reactors" Nichita (2021) introduces a pressurized reactor, PHWR, which takes advantage of the moderating characteristic of heavy water (i.e., D_2O) that allows these reactors to be fueled with natural (unenriched) or low enriched uranium. These reactors have design that incorporate either pressure-tube or pressure-vessel concepts. The chapter surveys those designs, with emphasis on the CANDU system, which are the most numerous version of PHWRs worldwide. The function and major design considerations of key components, such as the primary and secondary coolant circuits, the calandria (moderator vessel), the pressurized fuel channels, fuel bundles, control systems, on-line refueling and are discussed and illustrated with schematic type figures. Operational aspects for this type of reactor are considered.

A final type of water-cooled reactor, the "Water-cooled Graphite Moderated Reactor" known as RBMK (*Reaktor Bolshoy Moshchnosti Kanalnyy* or "high-power channel-type reactor") was intended to be covered in this section, but the chapter was unavailable for publication. Instead, the reader is directed to the description of the RBMK provided in Sich (2021) and Pioro et al. (2021). Here, the primary moderation for the nuclear chain reaction is performed by a static structure of graphite, while the fuel is cooled by water. While a number of these former Soviet Union reactors were shut down after the Chernobyl event, several are still providing electricity to the grid.

Two chapters on non-water-cooled reactors are provided in Section 3 of this encyclopedia, which is on the topic of Advanced Nuclear Reactor Concepts under R&D. However, the principles involved in sodium fast reactors ([Heidet, 2021](#)) and high temperature gas-cooled reactors ([Fütterer, 2021](#)) are notably similar to those types of reactors in operation today. Each of these has a primary and a secondary circuit with an intermediate heat exchanger serving as the interface between the nuclear heat transport path and a steam supply side. Gas-cooled reactors, with a low density working fluid for coolant, must operate at different temperatures and pressures than their water-cooled counterparts. Key components are also substantially different due to the working fluid, but since the specific power density is also low, safety systems are also different. Power reactors in operation today that use gas (CO₂) as a coolant also leverage a thermal neutron spectrum, and thus use graphite as a moderator.

Liquid metal cooled reactors are a subset of fast spectrum reactors, so have no need for a moderator in order to sustain the nuclear chain reaction. These reactors have relatively high power densities, but due to the high thermal conductivity of the metal coolant, have a high degree of passive safety capability inherent to the system. Due to the use of a metal coolant, however, unique systems are required to work with the coolant, and also to maintain and refuel the reactor, since the coolant is not optically transparent. While very few of these reactors are considered commercial power reactors, the technology is envisioned also for future applications, with a well-known capability for being able to operate on various fuel cycles (uranium, plutonium, actinide, etc.) and be fuel-self-sustaining (breeders).

An article on “Commercial Nuclear Power by Country” ([Hamon, 2021c](#)) is provided to give the reader an overview of the current usage of nuclear energy across the globe. While this information has the potential to change quite frequently, there are references provided that do continuously provide updates to this information.

“Nuclear Fuel and Control Element Design” ([Young, 2021a](#)) provides the reader with the nuclear and mechanical bases for the design of both nuclear fuel elements used in light water reactors and also the control rods, which provide the primary means for shutdown of PWR and BWR reactors. Mechanical and thermal-mechanical performance is analyzed by the complex interaction of the fuel material (fuel pellets) and the cladding, as a function of load condition and irradiation condition. Specified Acceptable Fuel Design Limits are derived from the performance limits on the assemblies in order to stay within their design criteria.

The article on the design of nuclear reactor cores was unable to be published in this chapter. This topic involves how the Specified Acceptable Fuel Design Limits (SAFDLs) are employed, along with economic objectives, to design the core arrangement of fuel and, when applicable, the control assemblies. This core arrangement, called a loading pattern, is the dominant method of designing a reactor core to achieve energy production targets, subjected to both reactivity limits for controllability of the core, as well as “thermal limits” derived from the applicable SAFDLs. The reader is directed to [International Atomic Energy Agency \(2019\)](#) for a general description of the design, analysis and safety principles of today’s commercial reactor cores.

Each reactor type employs a strategy for its economical and safe operation, consistent with the underlying technology. In “Reactor Operations” ([Young, 2021b](#)), the operation of PWRs and BWRs is discussed. The chapter describes operations from cold shutdown after refueling, to full power operation. This includes the approach to full power operation, the Technical Specification Requirements, surveillance activities during normal operation, operational strategies, off-normal response and reactor shutdown.

Given the multiple physics disciplines interlaced in a nuclear reactor system of engineering principles involved in the function of nuclear reactors, rather unique approaches are required for the solution of the system of equations governing reactor operation. The topic is discussed in the article “Operational Analysis Methods” ([Walters, 2021](#)). This article on steady-state reactor analysis covers the neutronics calculations at the lattice level to generate effective cross-sections (probability for specific neutron induced nuclear reactions) and how these cross sections and other nuclear parameters are transposed to 3-dimensional core simulation and coupled to integral thermal hydraulic analyses for application to core design and safety analyses.

The next chapter, “Transient Analysis Methods” ([Martin, 2021](#)), describes how thermal hydraulic time dependency and neutron kinetics is added to the reactor physics, in order to analyze the dynamics of safety performance during abnormal as well as design basis accident events. The industry standards and regulatory requirements that govern necessary attributes of the software, as well as the rigors required in establishing an evaluation model and appropriate uncertainties based on qualification demonstrations of the model are discussed. Both deterministic and stochastic techniques are introduced.

A separate chapter on the reactor containment building is provided, given the importance of this structure in assuring that radioactive release to the environment, in the event of an accident, is minimized. “Containment” ([Sharpe, 2021](#)) discusses the design of the structure, the technologies employed for effluent containment and the mitigating strategies used for reducing pressure and dynamic forces that can be created during severe accidents.

Because of the intimate coupling between the means of power production and transport and the safety principles and strategies of ensuring safety, substantial attention is paid to heat transfer systems in Nuclear Power Plants (NPPs). Adequate heat removal from the nuclear fuel by the heat transfer systems, both for full power operation and post-shutdown residual heat removal, prevents fuel failure and subsequent release of radioactivity. The article “Heat transfer systems” ([Kirkland, 2021](#)) explores many of the main heat transfer systems found in NPPs and provides a fundamental understanding of the physics and technology used in their design and operation.

The instrumentation and control (I&C) systems in a NPP, along with their enabling features, serve as the “central nervous system” of a NPP. In “Control and Instrumentation Systems” ([Upadhyaya and Wood, 2021](#)) the reader is introduced to the I&C architecture, comprising plant control, protection, and monitoring systems that provide information to various actuators and devices to ensure the safe and efficient operation of the plant, and to the operation and maintenance personnel for making timely decisions. This article focuses on the I&C systems used currently in light water reactor plants (PWRs and BWRs).

Systems, components, and structures that comprise a complete NPP and are not included in the nuclear steam supply systems as defined under 10 CFR 170.3 Definitions fall into the category of balance of plant systems. These systems include Fuel Storage and Handling Systems, Fuel and Auxiliary Pools Cooling System, Reactor Component Cooling Water System, Plant Service Water System, Drywell Cooling System, Control room habitability, Heating, Ventilation and Air Conditioning systems. A description of the design and function of these and some auxiliary systems is provided in “Design of the Balance of Plant” (Arcaro, 2021).

“Economics of Nuclear Energy” Rothwell (2021a) is a article intended to provide the reader with an understanding of the mathematics to correctly assess the costs involved in the construction, operation and decommissioning of NPPs, and how to assess the levelized cost of electricity based on capital intensive projects. The method of leveling the cost of electricity is key in making determination of competitiveness for a given technology, deployment scenario and fuel cycle.

A subsequent chapter, “Economic Challenges of Nuclear Power” (Rothwell, 2021b), explores the challenges of operating a nuclear power plant in markets with other electricity generation. These include regulated and deregulated electricity markets, as well as varying degrees of renewable energy generation priority dispatching, which can lead to grid pricing behaviors not conducive to capital intensive power generation technologies. Additional factors affecting the economic competitiveness of nuclear include political climate and the manner in which greenhouse gas emissions is being addressed in the various jurisdictions.

While the design requirements of nuclear reactors are almost synonymous with the safety criteria, a separate chapter on the evolution of these safety principles is provided in “Safety of Nuclear Reactors” (Brown and Seo, 2021). Reactor safety objectives are provided for anticipated operational occurrences, design basis accidents and severe accidents (beyond design basis), which forms the historical basis for licensing, particularly in the US. Current trends in regulatory framework, towards a more risk-informed approach, are also discussed. While Section 4 of this encyclopedia, “Safety, Licensing and “Decommissioning of Power Reactors” is entirely devoted to these topics, this article provides an overview focused solely on the relevance of safety regulation to commercial nuclear power.

“Pros and Cons of Commercial Power Reactor Designs” Parts 1 and 2 Piro and Duffey (2021a,b) compares the generation of electricity from nuclear power against other forms of energy generation used commercially. Since all forms of power generation must exist within the context of an electrical grid of some kind, the relative merits of the technology for energy production tends to be a function of the country in which it is deployed. These comparisons are described in these chapters through the examination of thermal efficiency and capacity factors, both of which are major contributors to the relative competitiveness between power plants measured by levelized cost of electricity, as discussed in the above chapters on economics. In addition, each nuclear reactor type has a certain set of advantages and disadvantages that influence the degree and trends in technology adoption, with local preferences having influenced the choices between reactor types of relatively similar capabilities of the current and past generation technologies. Future trends in the development of next generation reactors, with their higher thermal efficiencies owing to the higher working fluid temperatures, substantially close the gap with fossil fuel plants, while increasing safety compared to the prior generation nuclear technologies. The cost competitiveness of combined-cycle natural gas turbine power plants, driven by low commodity fuel costs and high thermal efficiency, is off-set by the key advantages of nuclear energy, which include cheap, reliable, high capacity factor base-load power, low risk to population per unit energy generated (in spite of perception from high profile accidents), low carbon emissions, and minor environmental impact.

The final chapter in this section provides the reader with an overview of the science, economics and trade-offs of the back end of the fuel cycle. “Management of Nuclear Waste – via Disposition or Transmutation” (Tsvetkov, 2021) describes the basics of repository characteristics and performance, introduces the concepts of safeguards and non-proliferation, and compares the options of disposition versus transmutation in order to reduce the hazards potential for the commercial nuclear waste stream.

It is hoped that the reader, having been given a brief overview of most of the major aspects of commercial nuclear power, will be equipped with enough knowledge to delve deeper into the relevant topical areas.

Glossary

AEC Atomic Energy Commission—The US agency in charge of nuclear energy.

AP1000 Advanced Plant 1000 MWe—a Westinghouse passive type Generation 3 PWR plant.

APR1400 Advanced Pressurized Reactor 1400 MWe—a South Korean (KHNP) PWR system.

BORAX The first series of boiling water reactor experiments at INL performed from 1953 through 1958.

Breeder A reactor that produces more nuclear fuel than it consumes. A fertile material, such as uranium-238, when bombarded by neutrons, is transformed into a fissile material, such as plutonium-239, which can be used as fuel.

Burnup A term for the specific thermal energy generated in the fuel material per unit mass of initial heavy metal (e.g., U).

BWR Boiling water reactor—A single coolant loop reactor type in which steam is generated directly inside the reactor vessel.

CP-1 Chicago pile 1—The first nuclear reactor. A graphite moderated natural uranium pile reactor.

CP-2 Chicago pile 2—The second nuclear reactor.

Criticality The normal operating condition of a reactor, in which a fission chain reaction is sustained at a given average fission rate. A reactor achieves criticality (and is said to be critical) when each fission event releases a sufficient number of neutrons to induce, on average, another fission event.

CVCS Chemical volume control system—A system that controls the primary.

DNB Departure from nucleate boiling—A PWR fuel clad design limit which represents the onset of film boiling resulting in a significant loss of heat transfer and increase in fuel clad temperature.

EFPD Effective full power days. A measure of the amount of energy generated if the reactor had run at full power for this number of days.

EFWS Emergency feed water system—An auxiliary system used to supply secondary feedwater to the steam generators when the normal feedwater supply is not available.

EPR Evolutionary pressurized reactor—A Framatome PWR system.

ESBWR The general electric economic simplified BWR reactor system.

Flux Flux is the neutron current in terms of neutrons/cm²-second.

LOCA Loss of coolant accident—An accident involving loss of primary cooling water to the reactor core.

Mark I The first PWR, a prototype of the naval reactor installed in the Nautilus submarine.

MTR Materials test reactor—A high flux water moderated reactor using high enriched uranium fuel located at the Idaho test lab.

Nautilus The first nuclear power submarine powered by a PWR.

Once-through SG A type of steam generator for PWRs in which the primary coolant enters at the top of the generator and is passed downward straight tubes to transfer heat to the secondary coolant.

Pressurizer The component of the RCS that maintains primary system pressure during normal operation.

RCP Reactor coolant pump—Use in PWRs to maintain flow of the primary coolant through the reactor vessel.

RCS Reactor coolant system—The primary coolant circuit of a PWR that provides pressurized coolant to the reactor core.

Reactivity A term expressing the departure of a reactor system from criticality. A positive reactivity addition indicates a move toward supercriticality (power increase). A negative reactivity addition indicates a move toward subcriticality (power decrease).

U-bend SG A type of steam generator for PWRs in which the primary coolant is passed through horizontal U-bend tubes to transfer heat to the secondary coolant.

U-tube SG A type of steam generator for PWRs in which the primary coolant is passed through vertical U-bend tubes to transfer heat to the secondary coolant.

VVER A Russian type Generation 2+ PWR using hexagonal fuel assemblies.

X-10 The Large Graphite Test reactor at Oak Ridge.

Introduction

Although the number of operational plants varies over time, according to the 2020 data from the [IAEA \(2020\)](#), 302 of the 442 operational nuclear power reactors in the world are based on the Pressurized Water Reactor (PWR) design ([Brown, 2021](#)). Moreover, 59 of the currently planned 75 power reactors are PWRs, with roughly 43 PWRs already under construction. The reason for this has been the proven reliability and relative simplicity of design and operation of this reactor design. And also due to the efforts of one man, Admiral Hyman G. Rickover. Although there are fewer BWRs ([Hamon, 2021](#)) operational in 2020, about 63, they constitute the second most popular design, thus worthy of discussion. There are currently four new BWRs under construction.

Early reactor development

The first reactor to achieve a self-sustained criticality was the CP-1 located at the University of Chicago which occurred on December 2, 1942. It was conceived and designed by Enrico Fermi and Leo Szilard. The core consisted of a $7.3 \times 7.3 \times 5.8$ m ($24 \times 24 \times 19$ ft) high cube containing 42.2 metric t (46.5 t) of Uranium in the form of alternating natural enriched Uranium metal and graphite blocks within a wooden frame. It was limited to a maximum power 200 W since there was no shielding or cooling. The subsequent experiments with this reactor allowed Fermi and his team to confirm the basic parameters of graphite reactor physics and kinetics and most importantly demonstrated that a nuclear reactor could be controlled and operated safely provided that reactivity was added in small increments.

CP-1 was operated for 3 months and then dismantled and moved to a site outside of Chicago in what is now known as Argonne National Lab. The reconstructed reactor, now known as CP-2 was slightly larger ($9.8 \text{ m} \times 9.8 \text{ m} \times 6.4 \text{ m}$ / $32 \text{ ft} \times 32 \text{ ft} \times 21 \text{ ft}$) with 47.2 metric t (52 t) of natural Uranium metal and included shielding that allowed the reactor to be operated at a maximum power of 10 kW. This reactor also had provisions for inserting materials for nuclear reactor testing. Initial criticality was achieved on March 20, 1943.

The experiments and tests performed on CP-2 led to the construction of the X-10 Large Graphite Test reactor at the Clinton Laboratory at Oak Ridge, Tennessee. The reactor consisted of a 7.3 m (24 ft) graphite cube surrounded by a 2.1 m (7 ft) thick shield of high-density concrete. The reactor core also contained several channels through which air was forced as the coolant. The X-10 achieved initial criticality on November 4, 1943 and was operated at a power of 1 MW, which was eventually increased to 4 MW.

The X-10 also had a large test stand on top of the reactor and was used for testing of materials for radiation shields and for measuring nuclear properties including the multiplication factor of fuel arrays. This assembly was used to investigate the multiplication factor of various arrays of natural Uranium rods in light water. Prior experiments with fuel arrays in light water separated by the relative wide spacing typical of graphite or heavy water critical assemblies had indicated a very low neutron multiplication factor. The X-10 experiments which contained unenriched Uranium rods in light water arranged in tight lattices revealed a multiplication factor close to critical (> 0.95), suggesting that it would be possible to achieve criticality in a similar light water lattice using slightly enriched Uranium. This led Dr. Alvin Weinberg, then director of Clinton, to suggest in 1944 that a power producing reactor could be achieved with Uranium rods in a pressurized water system in which the water acted as both moderator and coolant. High pressure would assure that the water would not boil and the core would remain fully moderated at all times. Weinberg stressed

the inherent safety of the design (as loss of coolant would cause loss of criticality and subsequent reactor shutdown) and that such a system could be based on existing technology. Weinberg and his team subsequently received a patent for the PWR reactor concept.

The X-10 light water experiments led to the design of the high flux Materials Test Reactor (MTR) in Idaho which was designed to operate at a power of 40 MWth and test the effects of high neutron and gamma flux on reactor materials. The reactor core of the MTR consisted of a $0.41 \times 0.71 \times 0.61$ m ($16 \times 28 \times 24$ in.) lattice of tightly spaced high enriched Uranium fuel plates in light water surrounded by a beryllium reflector. This configuration was originally suggested by Eugene Wigner in order to maximize the flux in the core. The fuel elements were 93% enriched uranium alloyed with aluminum, clad in aluminum, and formed into curved plates approximately 61 cm (24 in) long, 7.6 cm (3 in) wide and 0.16 cm (1/16 in) thick similar to the Shippingport seed assembly shown on Fig. 7A. The fuel plates were brazed into aluminum side plates to form a $7.6 \text{ cm} \times 7.6 \text{ cm}$ (3 in $\times$ 3 in) boxlike assembly. Control rods were inserted in spaces between the small assemblies to control and shutdown the reactor. Although the fuel plate configuration was less neutron efficient than arrays using fuel rods, the significantly improved heat transfer allowed for a smaller core and thus higher power density and neutron flux. The core was cooled by subcooled water at a flow rate $566 \text{ m}^3\text{-min}^{-1}$ (20,000 gpm). The MTR achieved criticality in 1952.

Investigation of various power reactor concepts continued at Oak Ridge, Argonne, and elsewhere. Based on these studies, the AEC in 1953 selected five out of some 80 different reactor concepts for further development based on their readiness for construction and on their potential economic competitiveness for commercial power production. The results in order of perceived long term commercial competitiveness were:

1. Homogeneous reactor
2. Fast Breeder reactor
3. Boiling Water reactor
4. Sodium cooled reactor
5. Pressurized Water reactor

Although the PWR was considered to require the least development time, it was rated lower based on estimates of long-term fuel cost since Uranium was considered an extremely rare resource (We now know that Uranium is far more plentiful and easily obtained than previously thought.).

Navy reactor development

The U.S. Navy recognized early on the benefits of using nuclear power as the propulsion plant for submarines and surface ships. The Navy requirements for a nuclear power plant were different than those for a power station that Oak Ridge and Argonne had been considering. Specifically, the Navy required that the reactor power plant be small enough to fit into a submarine and have low enough radiation release during normal operation such that the exposure to the crew during a prolonged voyage would be acceptable. Economics and efficient use of Uranium were not concerns.

In 1946, the Navy sent a small team of personnel with technical backgrounds to Oak Ridge for several months to learn about reactor development and to ultimately recommend the steps forward for development of nuclear power for Navy application. The leader of this team was Captain Hyman G. Rickover.

Rickover had a strong technical background (an Annapolis graduate in 1922, master's degree in electrical engineering at Columbia University in 1929) and was qualified to command submarines. Rickover had distinguished himself by his performance as head of the Navy's electrical section during WWII. Rickover had insisted on having full engineering design capabilities under his direct command so that he could make informed decisions on major technical issues. Rickover personally selected the contractors and worked directly with the responsible official in each company. He and his staff worked directly with the contractors in designing the equipment, and once the plans and specifications were established, he insisted that the manufacturers follow them to the letter. In the process, Rickover established close working relationships with major electrical equipment contractors such as General Electric and Westinghouse and earned the reputation of being a tough-minded, exacting, but reliable customer. Rickover's intuitive practical engineering sense, his tenacity, and his refusal to compromise on technical excellence, resulted in a huge improvement in ship electrical system reliability during World War II. These characteristics made him the right man to lead the Navy nuclear program.

During Rickover's time at Oak Ridge, Weinberg had discussed the PWR reactor concept with him. Weinberg stressed the advantages of the PWR concept and that a working prototype small enough to fit into a submarine could be designed and built relatively quickly using existing technology. Rickover encouraged Weinberg to continue engineering studies of the PWR concept for submarine application. Rickover believed that the problems required to design and build a nuclear power plant suitable for navy application were engineering problems not scientific ones that could best be solved by properly managed industry experts.

In April 1948 the Atomic Energy Commission (AEC), in response to mounting concerns over Soviet submarine advances, decided to initiate a formal high-priority project to design and build a nuclear power plant capable of powering a submarine. Rickover was assigned to oversee and manage the program. Argonne, to which the AEC had earlier transferred responsibility for reactor development was to lead the technical design.

Two concepts perceived as being capable of meeting the compact size requirement in the near term were selected for development as a submarine power plant: the liquid sodium cooled reactor and the PWR. The Navy had already commissioned Westinghouse to perform studies related to heat transfer systems with pressurized water and General Electric to perform similar studies with liquid

sodium, so these vendors were the natural choice to be the industry leads. Although it was recognized that substantial technology development was needed for the sodium cooled reactor, both Argonne and General Electric had already been performing studies to develop a large nuclear power plant using a fast sodium cooled breeder reactor. For the PWR little fundamental technology development was necessary, and as a consequence, the 1948 Navy assigned Westinghouse to perform the full engineering design of a prototype submarine PWR plant (Mark 1). Westinghouse would be required to “do all detailed engineering, produce the working drawings, procure the necessary materials, and construct the Mark I plant,” which would be a land-based prototype. Argonne would provide design and engineering data and, as the Commission’s agent, would approve the final working drawings prepared by Westinghouse. Rickover would be responsible to assure success of the overall project in meeting the Navy’s requirements.

The AEC procured the Bettis site near Pittsburgh and set up lab and engineering offices for the sole purpose of performing the research and engineering necessary to produce the prototype Mark 1 PWR. Per Rickover’s demand, Westinghouse assigned many of its top engineers to the site and hired top experts in metallurgy, nuclear physics, and other disciplines. Westinghouse subcontracted major components fabrication work (reactor vessel and internals, steam generators) to other firms (such as B&W).

Although most of the technology required for the Mark 1 was not new, there were several major design changes necessary to accommodate a nuclear power system within the confines of a submarine. Most marine boilers at that time consisted of assemblies of tubes carrying water. Surrounding the tubes were extremely hot gases derived from the combustion of fuel. Heat from the gases flowed across the walls of the boiler tubes and flashed the water to steam. Nuclear propulsion required radical changes in boiler design because the heat source was subcooled water rather than hot combustion gas. Flowing through the boiler tubes, the water would transfer its heat, through the tube, where it would convert the secondary water into steam.

Also, although steam propulsion systems in naval surface ships had been commonplace for almost a century, the Navy had always found steam impracticable for a submarine. One of the complicated problems Rickover and his team faced was how to arrange the steam generators, piping, turbines, and condenser within the limited confines of a submarine hull. Even if this could be accomplished, there was the important requirement of providing enough radiation shielding and air conditioning to keep radiation exposure and temperatures in the steam machinery areas down to habitable levels. For this reason, Rickover insisted on having the Mark 1 system be installed in an actual submarine hull section complete with turbine driven propeller shaft submersed in pool at the Idaho test site (See Fig. 1). Fig. 2 shows a schematic layout of the PWR submarine nuclear propulsion system.

Although many details of the Mark 1 core are still classified, it can reasonably be inferred from known details of the MTR and Shippingport designs that the reactor power rating was ~60–70 MWth delivering about 11.2 MW (15,000 hp) to the propeller shaft and that the core was a squat cylinder consisting of fuel elements essentially the same as those used in the MTR core (i.e., thin plates of high enriched Uranium alloy sandwiched within metal clad). Rickover decided to use Zirconium instead of aluminum for the clad and alloy material as he believed that it had better long term corrosion properties even though an economical process for obtaining pure Zirconium metal free from the neutron absorbing Hafnium had not yet been developed.

In order to meet the space constraints, the compact Mark 1 PWR system included a single B&W recirculating steam generator comprised of a straight tube and shell heat exchanger with riser and downcomer pipes connected to a separate steam drum similar to that used in Shippingport (see Fig. 3). The reactor coolant pumps employed a “canned” design in which the rotor and stators were completely sealed inside the pressure boundary and the induction motor outside. These canned pumps were chosen in order to eliminate the problem of high pressure primary coolant leakage through the pump shaft seals. These pumps had the added advantage of being much quieter than a normal rotary pump, a distinct advantage for a navy submarine.

The Mark 1 PWR went critical on March 30, 1953. For the next 2 months testing went on day and night. Rickover had insisted on a 100 h run at full power that would simulate a voyage from North America to Ireland and thoroughly test all components of the power train. Even though some problems occurred with the non-nuclear equipment during the simulated run, Rickover refused to terminate the test, but instead used this as an opportunity to see if such problems could be fixed or mitigated by the submarine crew.

Construction of the *USS Nautilus* began in 1952 at the Electric Boat shipyard in Groton, Connecticut. A nearly identical copy of the Mark I PWR (Mark II) was built and installed into the submarine. The Mark II PWR achieved criticality on December 30, 1954. In January 1955, the *Nautilus* began her first sea trials during which the nuclear propulsion system functioned flawlessly. The success of the Navy PWR nuclear propulsion system was firmly established in dramatic fashion during the summer of 1958 when the *Nautilus* made the first under ice transpolar voyage on a cruise from Pearl Harbor to Portland, England.

A sodium cooled reactor plant, developed by Argonne and GE was installed in the submarine *Seawolf* that was launched in June 1956. However, persistent problems with sodium coolant leaks led the Navy to eventually replace the sodium plant with a *Nautilus* type PWR plant. Thereafter the PWR plant became the standard propulsion plant for US submarines.

BWR early history

The earliest concept of using nuclear as a power source involved simply using an atomic pile to directly produce steam to drive an external turbine. However, there was great concern whether the rapid local changes in moderator and coolant density associated with bulk boiling might result in fuel rod failure or even worse in a rapid catastrophic power excursion. Unlike in the relatively simple case of the PWR, there were no tools able to predict the much more complex local nuclear thermal hydraulic coupling.

However, in 1950 Samuel Untermyer II of Argonne performed calculations that predicted that allowing the moderator to boil in the reactor core would actually make the reactor more stable to power excursions and easier to control. Untermyer’s calculations showed that the reactor could more easily follow load demand without the need for complicated control mechanisms. However,

Fig. 1 Mark 1 nautilus prototype PWR. Roddis LH and Simpson JW (1954) The nuclear propulsion plant of the USS nautilus SSN-571. In: Paper presented at the Annual Meeting of the Society of Naval Architects and Marine Engineers, New York, NY, November 10–13, 1954.

Fig. 2 Nuclear submarine propulsion system.

Fig. 3 Shippingport reactor system description. Bettis (1957) *Description of the Shippingport Atomic Power Station*, WAPD-PWR-970.

given the state of the analytical tools, tests were needed to confirm Untermeyer's predictions. Untermeyer convinced his boss, Walter Zinn, of the advantages of the boiling-water-reactor concept, and they were successful in getting the AEC to authorize small-scale tests at the Idaho National Reactor Test Site. The test reactor (BORAX-I), assembled from components scavenged from other test was installed on the ground, without any cover with the control room in a small trailer parked half a mile away.

From May 1953 for the next 14 months, Untermeyer and his team would inflict this collection of scrounged parts to every transient imaginable. Over 200 transients and power excursions were investigated with the last one being a prompt critical event that melted the reactor core but did not destroy the reactor vessel. These tests proved that the Boiling Reactor would be controllable and even in the event of a worst-case transient could be designed to limit release of radioactivity to the environment.

Over the next several years further BWR test reactors (BORAX-II, BORAX-III, BORAX-IV, and finally BORAX-V, a full power reactor prototype), were built and tested that confirmed Untermeyer's prediction of an inherently safe, self-controlling boiling water reactor (In fact, the BORAX-III reactor has the distinction of being the first nuclear power plant to fully support a public electric grid in that it supplied electricity for the entire town of Arco, ID for 1 h on July 17, 1955.).

These efforts were followed by two key developmental plants, the Experimental BWR and the Vallecitos BWR, which provided important and timely operational information for the ultimately development of the Dresden I BWR (Fennern, 2018), described in more detail in the subsection below labeled "Commercial Power Plants."

Shippingport

Until 1953, all nuclear reactor research had been classified, as the ultimate purpose had been mostly defense related. However, in 1953 President Eisenhower announced that the US would declassify and release the technology necessary for civilian and international peaceful application of nuclear power in his famous Atomic Power for Peace speech to the United Nations. With that, he opened the door for commercial application of nuclear power.

In March 1953, the U.S. National Security Council canceled plans for a large land-based prototype PWR reactor for an aircraft carrier. The AEC asked the President and Congress to redirect the funds previously approved for the project to be used for construction of a prototype civilian nuclear power plant. The AEC would build and own the nuclear reactor and would provide trained reactor operators to a private utility company which would own and operate the turbine-generator and balance of plant. Congress approved and the civilian power project based on the aircraft carrier reactor was assigned to Admiral Rickover. Rickover chose to work with Westinghouse and Bettis for the final design and fabrication.

In July 1953, the AEC established the general specifications for the prototype nuclear power plant. It should generate at least 60 MWe using slightly enriched uranium fuel and the coolant demineralized ordinary water. The life of the fuel elements was to be as long as possible and refueling was to take place with a minimum shutdown period. The AEC believed that target power rating

of 60 MWe was a reasonable extrapolation of existing technology. Going higher would mean larger components, higher costs, and would provide little additional data than provided by a 60 MWe plant.

Admiral Rickover and his team recognized that the project had two purposes: to show that a central station nuclear power plant could function on a utility network, and to provide technical information to advance civilian power reactor technology. He was well aware that he was setting precedents for a new industry and thus had to apply a conservative design philosophy that would guarantee the highest standard of safety. It was a responsibility he took seriously. No part of the station's design, development, construction, operation, or personnel escaped his oversight. Rickover insisted that a Naval Reactors representative who would have the authority to order reactor shutdown if safety was compromised, be present at all times during initial startup and early operation of the plant.

Although many utilities expressed interest in the project, the Duquesne Light Company of Pittsburgh offered at no cost, a site it owned at Shippingport, a small town on the Ohio River about 25 miles northwest of Pittsburgh. Duquesne Light proposed to build the turbine generator part of the station, and operate and maintain the entire facility and purchase the steam at the relatively good price of 8 miles/kW-h. The AEC would supply the reactor system and the nuclear fuel. The combination of Duquesne Light, the Shippingport site, Westinghouse, and Bettis all in the Pittsburgh area provided strong incentive to accept the Duquesne offer and locate the project there.

Shippingport would not be the first nuclear plant to put electricity to a public power grid. The EBR1 in Idaho had produced token amounts of power in 1951, the Russians built a small power plant at Obninsk in 1954, the BW4 provided electricity to a small Idaho town in July 1955, and the Calder Hall station supplied power to the United Kingdom national distribution system in October 1956. But in all these cases the reactor was primarily designed and operated for military purposes. Shippingport was the first full-scale plant designed and operated solely for the purpose of producing electricity for civilian use and advancing civilian reactor technology.

The Shippingport PWR system (Fig. 3) was essentially an enlarged four-loop version of the Mark 1/*Nautilus* system. The reactor vessel (Fig. 4) which was the largest that could be fabricated at that time (by Combustion Engineering) stood 18.3 m (60 ft) high. The system employed two different types of steam generators, two Foster-Wheeler straight horizontal steam drums similar to those used in large fossil power plants, and two B&WU-bend horizontal generators (Fig. 5) similar to those used in the *Nautilus*. The intent of including both types was that operating experience obtained from Shippingport would be used to select the steam generator design for future PWR plants. Although not normally used for reactivity control, boric acid could be injected into RCS as a means to achieve cold shutdown in the event of a stuck control rod. Emergency core cooling was achieved by redirecting the steam generator feedwater pumps to inject water directly into the reactor hot legs instead of the steam generator. The reactor containment building consisted of a mostly below ground spherical steel shell surrounded by concrete for extra radiation shielding.

Fig. 4 Shippingport reactor vessel. Bettis (1957) *Description of the Shippingport Atomic Power Station*, WAPD-PWR-970.

Fig. 5 Shippingport B&WU-bend steam generator. Bettis (1957) *Description of the Shippingport Atomic Power Station*, WAPD-PWR-970.

For the reactor core design, the primary goal was to achieve a long life core using low enriched Uranium. The obvious choice was to use the Uranium metal plate configuration previously used in the Mark 1 and Nautilus, especially since the plate design had good heat transfer characteristics and had performed well in there. But Rickover was concerned about the potential for corrosion of the Uranium metal fuel during long period of high power operation. The Rickover team decided to use a new fuel material consisting of Uranium dioxide (UO_2) pellets contained within thin Zircaloy 2 rods. Since little was known of the properties of UO_2 under irradiation and UO_2 had never been produced using enriched Uranium, it was decided that the power in the UO_2 assemblies should initially be limited, but then allowed to increase over time if there were no cladding integrity problems.

In order to meet these requirements, Shippingport employed a novel core "seed-blanket" design devised by Alvin Radkowsky of NRR in which 32 high enriched "seed" assemblies would provide the excess neutrons needed to drive 113 naturally enriched "blanket" assemblies (See Fig. 6). The seed assemblies for the first core would consist of a six-foot stack of fuel plate elements similar to those previously used in the Mark 1 and Nautilus (See Fig. 7A). The blanket assembly would consist of a 1.8 m (6 ft) stack of 26 cm (10.25 in) tall sub-assemblies of 12×12 arrays of Zircaloy 2 rods containing UO_2 pellets (Fig. 7B). The initial power generated in the blanket assemblies would be low, but would rise as plutonium was generated in the blanket assemblies by excess neutrons produced in the seed assemblies. Another advantage of this core design concept was that reactivity and power distribution control could be achieved by use of hafnium cruciform shaped control rods only in the 32 seed assemblies. Even without control

Fig. 6 Shippingport seed-blanket core 1 loading pattern. *FEDL*, failed element detection and location conduits; *FMI*, flow measurement instrumentation. Bettis (1957) *Description of the Shippingport Atomic Power Station*, WAPD-PWR-970.

rods the seed assemblies could achieve criticality only in the presence of some blanket assemblies to reflect and multiply some of the neutrons generated in the seed assemblies. The seed assemblies would be periodically replaced in order to obtain high burnup in the UO_2 fuel. The seed assemblies could be replaced without removing the head and reactor internals through refueling ports in the upper head (Fig. 4).

Shippingport achieved criticality on December 2, 1957 and operated flawlessly throughout its life. Core 1 was refueled with three additional seed regions and operated for a total of 1158 effective full power days (EFPD) and generated a total electrical output of 1.8×10^9 kW-h, half of which was ultimately generated by the UO_2 blanket assemblies. The final average burnup of the UO_2 assemblies was 8500 MWD/MTUO₂ with a peak UO_2 pellet burnup of 37,000 MWD/MTUO₂.

In 1965, Shippingport implemented the first power reactor uprate to 150 MWe (505 MWth). To support this uprate, the second Shippingport core used fuel elements consisting of UO_2 sandwiched between Zircaloy-4 plates for both the seed and blanket assemblies. This configuration provided better heat transfer to support the increased power density. The seed contained a mixture of highly enriched UO_2 and ZrO_2 , while the blanket contained UO_2 of natural enrichment. Core 2 also incorporated the first use of burnable absorbers in the form of borated stainless steel plates in the corners of each fuel assemblies. The Shippingport Core 2 operated with one seed refueling from April 1965 until February 1974 for a total of 992 EFPD.

In 1977, Shippingport began operation with its third and final seed-blanket core designed as a thorium-232 to uranium-233 "Light Water Breeder" in which excess neutrons from U-233 fission would convert the non-fissionable Th-232 into more U-233. The data and experience gained from operation of this core was crucial to the development of Thorium-based fuel cycle technology.

Shippingport ceased operation in October 1982. Duquesne subsequently built two additional PWRs (Beaver Valley 1 & 2) on this site.

Overall, the Shippingport project contributed immensely to the development of nuclear power plant components, fuel element design, and analysis methods, and established the specifications, procedures, and standards for industry to follow in constructing and operating large nuclear power plants.

Commercial power plants

By the 1960s the various companies (Westinghouse, GE, CE, B&W) who had participated in the Naval and Shippingport reactor programs were well-positioned to develop and sell commercial nuclear systems of their own. And the Shippingport experience had demonstrated that utilities with properly trained personnel could safely operate a nuclear power plant. Westinghouse, B&W, and Combustion Engineering chose to develop and market the PWR concept, while GE chose the BWR. The national labs thereafter mostly focused their efforts on developing advanced reactor concepts, such as the fast breeder reactor.

Commercial PWR Development.

The 150 MWe, 485 MWth, Yankee Rowe plant, located in Rowe Massachusetts, containing a Westinghouse PWR was the first fully commercial nuclear power plant, owned and operated by a private company, to achieve criticality on January 16, 1961. Although nominally based on the Shippingport design, there were some important differences:

- An above-ground spherical steel containment building.
- Reactor coolant inlet and outlet nozzles above the core to facilitate the introduction of emergency core cooling water (See Fig. 8).
- A dedicated Emergency Core Cooling System.
- Use of boric acid in the primary coolant as a means of normal reactivity control.
- Ability to inject boron into the coolant to aid in normal shutdowns and was also used in the safety injection system (later known as the emergency core cooling system).
- Four Vertical U-tube Steam Generators.
- Uniform slightly-enriched UO_2 contained in bundles of 305 full length (90 in.) fuel rods instead of the stacked seed and blanket configuration.
- Stainless steel fuel rod cladding instead of Zircaloy (implemented in the early cycles as a cost reduction measure, but was later replaced by Zircaloy).
- Silver-indium-cadmium cruciform control rods (instead of hafnium) that were inserted in the gaps between the fuel assemblies. These rods also had a long Zircaloy-2 follower tip that would remain in the reactor core even when the poison region of the rods were fully withdrawn in order to minimize power peaking that would otherwise occur if the gaps were empty.
- Elimination of the reactor head refueling channels.
- Annual refueling cycles.
- Movable in-core cobalt wire flux detectors.

Fig. 8 Yankee Rowe reactor vessel. Westinghouse Electric Company (1967) *Engineering and Metallurgical Evaluation of the Yankee Core 1 Spent Fuel*, WCAP-6084.

By 1963, the stage was set for the first nuclear power stations that could function as large base load units in multi-station grids on a nearly equal availability factor and operational cost footing with coal- or oil-powered units. The first "full scale" stations were the three-loop 436 MWe San Onofre 1 PWR (Westinghouse), the 275 MWe Indian Point 1 (1962, B&W), and the four-loop 616 MWe Connecticut Yankee PWR (Westinghouse) Nuclear Generating Station.

Since these early days nearly 300 PWR power plants have been built throughout the world, all based on the design established for the Mark 1/*Nautilus* and Shippingport concepts. Current PWR designs are typically 1000–1400 MWe (3500–4000 MWth) with significant improvements in accident mitigation features. Recently there has been a drive to standardize nuclear power plant design in order to facilitate construction and licensing approval. Current standard PWR designs include the Westinghouse AP1000, the Framatome EPR, the Korean APR1400, and the Russian VVER1000. These standardized designs are being used as the template for the construction of a fleet of PWRs in several countries.

Commercial BWR development

The evolution of the BWR power plant occurred in parallel to that of the PWR since there were obvious significant commercial advantages of the BWR design including:

- Lower capital cost than the PWR due to single coolant loop design and smaller containment.
- Large negative moderator void coefficient of reactivity and reactivity control by the recirculation pumps makes the plant easier to load-follow than a PWR.
- Significantly reduced operating pressure (from about 2250 psia down to 1000 psia) that simplified the reactor coolant system and allowed for a smaller primary containment.
- Elimination of boric acid from the reactor coolant system significantly reduced corrosion of all the RCS components and assures that the moderator temperature feedback is negative at operating conditions.

The first commercial-size BWR plant was the Dresden Unit 1, which began operation in 1960. This was, in large part, pursued by GE and the Commonwealth Edison Company of Chicago following the success of the BORAX experiments, but preceded by two smaller scale projects; the experimental BWR (EBWR) which started construction in 1954 at ANL in Illinois, and went operational in 1956, as well as a developmental plant constructed by GE at its Vallecitos Atomic Laboratory near Pleasanton, California, the Vallecitos BWR (VBWR) became the first privately built nuclear reactor that provided electricity to a public grid in 1957. Cutaway illustrations are provided in Fig. 9A and B for the EBWR and VBWR, respectively (Fennern, 2018). The VBWR, in fact, was the first power reactor to obtain a commercial license (Power Reactor License No. 1), which helped promote the commercial expansion of the BWR in the US with the Dresden and Humboldt Bay plants, among others, and also internationally with the Dodewaard reactor, the first GE BWR generating ~58 MW in the Netherlands from 1969 through 1997, and the first large nuclear reactor in Germany, Gundremmingen (KRB) Unit A, producing ~237 MW from 1966 through 1977.

The table below (GE Hitachi Nuclear Energy, 2007) illustrates the history of commercial GE BWRs as they followed the Dresden Unit 1's success (Table 1).

To highlight the technical progression toward the modern versions of the GE BWR, it should be noted that the Dresden 1 BWR/1 system did not include the traditional direct steam cycle, but employed a steam drum and heat exchanger to produce turbine steam in a secondary system, basically a steam generator.

It wasn't until the mid-1960s and the BWR/2 at Oyster Creek that the steam generator concept was eliminated. The distinctive characteristics of the Generation II BWRs (BWR/2 through BWR/6) include direct-cycle, forced circulation, internal steam separation and a higher power output. Fig. 10 illustrates these distinctive BWR characteristics for the BWR/6 and the progression to the ABWR (Fennern, 2018). It should be noted that these evolving features were made feasible in large part due to improvements in nuclear fuel bundle and core design, leading to a higher power density (BWR/4, Vermont Yankee). Likewise, key thermal hydraulic advancements that facilitated this evolution included the transition from external loop plants to jet pumps (BWR/3, Dresden 2), and subsequently to reactor internal pumps (ABWR). GE/Hitachi's future technology strongly favors the use of natural circulation in currently marketed and future reactor concepts such as the Economic Simplified BWR (ESBWR) and the BWRX-300, a ~300 MWe small modular reactor (SMR).

Fig. 9 Early developmental BWR prototypes (A) EBWR plant cutaway (Fennern, 2018). (B) VBWR plant cutaway (Fennern, 2018). From Kramer, 1958.

Table 1 Evolution of the GE BWR (GE Hitachi Nuclear Energy, 2007)

<i>Product line</i>	<i>First commercial operation date</i>	<i>Representative plant Characteristics</i>
BWR/1	1960	Dresden 1 Initial commercial-size BWR
BWR/2	1969	Oyster creek Plants purchased solely on economics Large direct cycle
BWR/3	1971	Dresden 2 First jet pump application Improved ECCS: spray and flood capability
BWR/4	1972	Vermont Yankee Increased power density (20%)
BWR/5	1977	Tokai 2 Improved ECCS Valve flow control
BWR/6	1978	Cofrentes Compact control room Solid-state nuclear system protection system
ABWR	1996	Kashiwazaki-Kariwa 6 Reactor internal pumps Fine-motion control rod drives Advanced control room, digital solid-state microprocessors Fiber optic data transmission/multiplexing Increased number of fuel bundles Titanium condenser Improved ECCS: high/low pressure flooders

In addition to the above noted advantageous features of the BWR, there has also been a substantial evolution of the BWR fuel assembly design, in comparison to the PWR. While the original BWR fuel resembled that of a PWR with the fuel rods assembled with fixed spacing throughout the entire height, this resulted in a relatively low fuel utilization (burnup) compared to PWRs due to the reduced moderation caused by the steam in the upper core region. This led to significant evolutionary changes in BWR fuel designs, such as variable pitch, part-length fuel rods, and internal water holes, that were developed to compensate for the two-phase flow impact upon moderation. Likewise, the complexity of fuel and burnable absorber radial/axial loading arrangements has grown exponentially so that today's BWR fuel assemblies are essentially optimized to specific plants and operating cycles. This has ultimately resulted into greatly improved fuel utilization for modern BWRs more comparable to that of PWRs.

Dimension wise, however, the BWR reactor vessel and active core are much larger than for a PWR of equivalent total power. This is due to the lower core power density necessary to maintain adequate margin to the fuel design limits in a BWR, and is an attribute that made the BWR unsuitable for submarine propulsion, where size and space considerations are paramount.

The containment for the BWR, given that is a more active structure than that for PWRs, has also evolved considerably over time. The first BWR containment systems were spherical steel structures and dry. These were superseded by the evolution of the Mark I, II, and III containments which included a pressure suppression pool that offers important advantages; primarily as a heat sink for steam from various sources such as LOCA (Loss of Coolant Accident) blowdown, safety/relief valves, and reactor discharge steam. The in-containment suppression pool also serves as a secondary source of water to support the Emergency Core Cooling System (ECCS), isolation make up, and cooling pumps. **Figs. 11A and B (Fennern, 2018)** provide the contrast between the early Mark I "inverted light bulb" drywell with the toroidal suppression pool, and the Mark III containment vessel used for the BWR/6 which exploited a simpler right circular geometry that combines a steel containment or liner surrounded by concrete shield or vessel, respectively.

As BWRs evolved from their first generation, concerns grew about the ability to provide sufficient core cooling during a LOCA, and the early BWRs did not have the ECCS, although the BWR/2 had limited capacity and spray, and some BWR/1 units were retrofitted to have some forms of ECCS. It wasn't until 1973 when US 10CFR50.46 defined the ECCS performance criteria, which limited peak clad temperature to 1200 °C, that prompted multi-layered approach to the ECCS, that for the BWR/5 and BWR/6 includes 2 ECCS pumps, a Residual Heat Removal (RHR) pump for Low Pressure Coolant Injection (LPCI), a Low Pressure Core Spray (LPCS), and a High Pressure Core Spray (HPCS) on a dedicated diesel generator.

Although the BWR had its roots with GE in the United States, BWRs were also successfully built and operated around the world, including Mexico, Netherlands, Italy, Spain, Switzerland, Germany, Japan, India, and Taiwan. In fact, in several instances, the original GE BWR technology was advanced by other organizations, such as by Kraftwerk Union AG, in Germany, originally founded by Allgemeine Elektrizitäts-Gesellschaft (AEG) and Siemens, which contributed to key modernized features of the Series 72 Gundremmingen

Fig. 10 Evolution to the BWR/6 and ABWR. (A) Direct Cycle BWR/6 (typical of BWR/6) (Fennern, 2018 from BWR/6, 1980). (B) ABWR reactor assembly and coolant flow path (Fennern, 2018). Units B and C that began operation in 1984. In Sweden, the first western commercial LWR was designed, built, and operated without licensing from US vendors, where the Oskarshamnverket Kraftgrupp AB (OKG) consortium majority owned by Sydkraft ordered the construction of the Oskarshamn Unit 1 BWR from ASEA-Atom, which went operational in 1972 and was followed by Units 2 and 3 connected to the grid in 1974 and 1985, respectively. In Asia, two BWR/1 reactors were constructed at the Tarapur Atomic Power Station and brought online in 1969, while in Japan, several BWRs ranging from BWR/2 through BWR/5 were constructed, beginning with the Tsuruga BWR which went operational in 1970. One of the highlights of international cooperation constitutes the programs

Fig. 11 Transition from the Mark I–III containment. (A) Mark I containment (Fennern, 2018). (B): Mark III containment (Fennern, 2018). Courtesy GE-Hitachi Nuclear Energy.

among GE, Hitachi, and Toshiba, which in addition to providing improvements for the BWR ultimately led to the design and construction of the Kashiwazaki-Kariwa ABWR in 1996, and three additional ABWRs now operational plus two more under construction in Japan, and two in Taiwan.

Summary

Modern PWR and BWR power plants have proven highly successful as a reliable, cost effective, and safe source of electrical power for the public grid. These modern designs were the result of many years of design improvements based on experience from early tests and prototype designs. And in both cases both of these concepts owe their success to the vision and relentless drive of a few individuals who were key in convincing others to commit to the long term development necessary to bring to fruition.

Glossary

Actinide The series of elements from atomic number 89 (actinium) through 103 (lawrencium), thus including uranium, neptunium and plutonium.

Binary nuclear reaction Change in the identity or characteristics of an atomic nucleus (target) induced by bombarding it with a nuclear particle (projectile).

Chain reaction A reaction yielding products that initiate reactions of the same kind.

Criticality (critical state) An equilibrium (time-independent) state of a neutron population.

Cross section Microscopic cross section is a measure of the probability of interaction of a neutron with a single nucleus. Macroscopic cross section is a measure of the probability of interaction of a neutron within a specific concentration of nuclei (within a volume of material).

Delayed neutrons Neutrons emitted by excited fission products in decay chains formed following fission reactions.

Electron volt (eV) A unit of energy $1 \text{ eV} = 1.6022 \times 10^{-19} \text{ J}$. $1 \text{ keV} = 10^3 \text{ eV}$; $1 \text{ MeV} = 10^6 \text{ eV}$.

Evaluated nuclear data files Digitized and analyzed collections of nuclear data sets gathered from all available experiments and nuclear models that are assessed (evaluated) to be uniquely describing relevant nuclear reactions.

Fast reactors Nuclear reactors characterized by dominance of fission reactions induced by high energy (fast) neutrons.

Fission fragments Fully ionized parts of a heavy atomic nucleus formed directly in a fission reaction either induced by interacting neutron or occurred spontaneously.

Fission neutrons Neutrons emanating in fission reactions.

Fission products Fully neutralized fission fragments formed in fission reactions and going through decay chains.

Fission reaction (fission) Subdivision of a heavy atomic nucleus, such as that of uranium or plutonium, into two or more fragments. The reaction results in a yield of a large amount of energy. It may occur spontaneously (spontaneous fission) or may be induced by the excitation of the nucleus with a variety of particles (induced fission).

Fission spectrum Energy distribution of neutrons (fission neutrons) emanating in fission reactions.

Multiplication factor A ratio of the number of neutrons in a generation to the number of neutrons in the preceding generation.

Neutron economy A relationship between the neutrons created (neutron production) in a configuration and the neutrons lost (neutron loss) through various nuclear processes (absorption, leakage out, etc.).

Nuclear fission chain reaction Series of nuclear fission reactions where each reaction is initiated (induced) by a neutron released in a previous reaction.

Nuclear physics The field of science that is focused on atomic nuclei, their structures and interactions.

Prompt neutrons Neutrons emitted by the fission event almost instantly (within 10^{-13} s).

Thermal reactors Nuclear reactors characterized by dominance of fission reactions induced by low energy (thermal) neutrons.

Fission reactions

In the fission process, heavy nuclei of actinides are split into several (usually two) light nuclei of fission fragments while emitting a number (typically 2 or 3) prompt neutrons (Klay, 2021). Combined masses of these fragments and emitted neutrons are less than masses of fissioning actinides. This results in the significant energy release. Today's nuclear energy technologies are the culmination of decades of development efforts to mature the means to induce fission reactions and harvest their energy release (Adler and Von Halban, 1939; National Research Council, 2013).

The challenge is to induce fissions of heavy nuclei. Some actinides heavier than plutonium have significant probability to undergo radioactive decay via spontaneous fission. However, for practical applications, it is necessary to hit heavy nuclei with sub-atomic particles, such as neutrons, to produce compound nuclei in extremely highly excited states. The unstable compound nucleus may release its excitation energy through a variety of decay reactions including the fission process (IAEA, 2000; Klay, 2021).

Any very heavy nucleus can be made to fission accompanied by a net release of energy if hit sufficiently hard by some incident particle. However, very few nuclides can fission by the absorption of a neutron with negligible incident kinetic energy. Such neutrons typically are thermal neutrons, neutrons which have lost almost all of their kinetic energy and are moving with speeds comparable to the speed of the thermal motion of the ambient atoms. At room temperature, thermal neutrons have kinetic energies lower than 1 eV. Neutrons with higher energies are called epithermal neutrons. Neutrons still carrying energies closer to their initial fission neutron energies are called fast neutrons.

The binding energy of the thermal neutron in the compound nucleus provides sufficient excitation energy that the compound nucleus can split apart (Klay, 2021). Nuclides, such as ^{235}U , ^{233}U , and ^{239}Pu , that fission upon the absorption of a slow moving (thermal) neutron, are called fissile nuclei. They play the key role in nuclear reactors because probabilities of fissions to occur are much higher at lower energies. On the other hand, nuclides that fission only when they are hit by neutrons with energies closer to fission neutron energies (fast neutrons), such as ^{238}U and ^{240}Pu , are called fissionable, they undergo fast fissions. Typically, these fissionable nuclides are characterized by high probability to capture thermal and epithermal neutrons, converting them into fissile nuclides through transformation chains (Kawano et al., 2008; Shusterman, 2021).

In addition to prompt fission neutrons emitted directly in the fission process, small fractions of fission neutrons, called delayed neutrons, are emitted by nuclides in decay chains of fission products (IAEA, 2008; Tudora and Hamsch, 2010; Klay, 2021). Delayed neutrons released per fission events depend on the fissioning nuclide and the energy of the neutron inducing the fission (Oblozinsky, 2009; Rudstam et al., 2002; Klay, 2021).

All fissionable nuclides produce distributions of prompt fission-neutron energies which go to zero at low and high energies and attain maxima around 0.7 MeV (Staples et al., 1995; Klay, 2021). The energies of the prompt fission neutrons are described by a fission spectrum distribution function, similar to that shown in Fig. 1 for prompt fissions in U^{235} . The average energy of prompt fission neutrons is about 2 MeV (Capote et al., 2016; Haight et al., 2009; Kapoor et al., 1963). Delayed neutrons, emitted through decay chains of fission products, carry considerably lower kinetic energies of a few hundreds of keVs (Wilson and England, 2000).

Cross sections

As a beam of neutrons travels through matter, the intensity of the neutron beam will decrease as neutrons are removed from the beam by absorption and scattering processes. The primary form of neutron absorption in a thermal system is the capture reaction, in the form of an (n,γ) interaction. This implies that a nucleus in the system will absorb one of the beam's neutrons and radiate

Fig. 1 Prompt neutron energy spectrum.

a gamma particle. The probability, or measure of, this neutron removal reaction occurring depends on the material the neutron is traveling in, that material's temperature and density, and the energy of the neutron. The "probability" is typically referred to as that material's cross section, for the given reaction type ((n, γ) in this case).

The cross section can vary greatly as a function of neutron energy, and is extremely significant to the understanding of the nuclear aspects of reactor simulation and operations.

The probability of a collision event is dependent not only upon the nucleus type, but on the relative velocity of the neutron and nucleus as well. The interaction rate in a bulk sample will also be proportional to the density of nuclei, N (number $\bullet$ cm $^{-3}$), and neutrons, n (number $\bullet$ cm $^{-3}$). Hence, the reaction rate in such a sample can be written as:

$$R(E_n) = \sigma_j(E_n)Nn(E_n)v \quad (1)$$

where R = reaction rate (reactions $\bullet$ cm $^{-3}$ $\bullet$ sec $^{-1}$), E_n = neutron energy (electron-volts), v = neutron speed (cm $\bullet$ sec $^{-1}$), σ_j = microscopic cross section for reaction type j (cm 2).

The proportionality constant σ is called the microscopic cross section and is a measure of the probability of interaction of a neutron with a single nucleus. The dependence of σ on neutron energy is explicitly shown in Eq. (1), but will henceforth be omitted for simplicity. Since collision reaction probabilities depend upon the relative velocity of neutrons and nuclei, the thermal motion of nuclei must be accounted for as low neutron energies (i.e., when the relative velocity of the neutron and nucleus may be significantly different from the neutron velocity), and at energies where the cross section varies rapidly. The latter situation is an important consideration for resonance absorption and, as will be discussed later, is usually accounted for by defining an "effective" cross section.

Each characteristic neutron interaction has an associated neutron cross section and is denoted accordingly:

- Elastic scattering σ_s .
- Inelastic Scattering σ_i .
- Radiative capture σ_γ .
- Charged-particle capture σ_α , σ_p .
- Fission σ_f .

The total cross section:

$$\sigma_t = \sigma_s + \sigma_i + \sigma_\gamma + \sigma_\alpha + \sigma_p + \sigma_f + \dots \quad (2)$$

measures the probability that an interaction of any type will occur when a neutron collides with a particular target nucleus.

The sum of the cross sections of all capture reactions is known as the absorption cross section, denoted by σ_a :

$$\sigma_a = \sigma_\gamma + \sigma_\alpha + \sigma_p + \sigma_f + \dots \quad (3)$$

Note that the fission cross section has been included in Eq. (3). While fission is probably the most significant single reaction type in a nuclear fuel system, it is nonetheless a constituent component of both the absorption and total cross sections.

The product $\sigma \bullet N$ arises frequently and is denoted as:

$$\Sigma \equiv N\sigma \text{ (cm}^{-1}\text{)} \quad (4)$$

While the microscopic cross section, σ , characterizes the probability of interaction with a single nucleus, Σ characterizes the probability of interaction with a specific concentration of nuclei and is therefore called the macroscopic cross section.

The product $n \bullet v$ is called the neutron flux and is assigned the symbol:

$$\phi \equiv nv \text{ (neutrons} \bullet \text{cm}^{-2} \bullet \text{sec}^{-1}\text{)} \quad (5)$$

Although in other physical systems the term flux is ordinarily used to denote a vector quantity, here flux is a scalar quantity and can be thought of as the total neutron path length per cm^3 per sec (i.e., neutron $\text{cm}/\text{cm}^3 \text{ sec}$). It logically follows that Σ is just the probability of interaction per unit path length, and Eq. (1) can be rewritten as:

$$R = \Sigma\phi \quad (6)$$

The term “thermal” refers to the neutron energy at which the cross section is evaluated, namely 0.025 eV (2200 m/s), the most probable energy for neutrons in thermal equilibrium with the system constituents at 20 °C. Materials that exhibit large absorption cross sections, such as B^{10} (used to control the reaction) or Xe^{135} (a product of the fission reaction) are frequently referred to as neutron poisons.

Fig. 2 shows the energy dependence of the total cross section for three important isotopes. The majority of the cross section is σ_a for B^{10} and U^{238} since the reactions are dominated by absorption. The cross section behavior of B^{10} is commonly called a “ $1/v$ ” absorber because the cross section is inversely proportional to the neutron velocity over a wide range of energy. As is typical of heavy nuclei, U^{238} exhibits a number of sharp absorption peaks. These peaks are referred to as resonances, since they occur at those neutron energies for which the combined energy of the neutron and nucleus match one of the naturally occurring energy levels of the compound nucleus (in this case U^{239}). The well-defined resonances at upper thermal and intermediate energies are called resolved resonances. Notably, there are thousands of unresolved resonances at higher energies which cannot be characterized by well-defined parameters and have to be accounted for together using reactor rate conservation together with stochastic approaches.

Fig. 2 Total cross sections for B^{10} , U^{235} and U^{238} as a function of incident neutron energy.

Fig. 3 Concept of Doppler resonance broadening.

The cross section of U^{235} is dominated by the fission cross section at low energies, and this is two orders of magnitude higher than the total cross section for the other constituent isotope of uranium (U^{238}).

The cross section in the high energy end of the plot is fairly small. The epithermal region energy range (between thermal and fast energies) for the U^{238} capture cross section is characterized by many large resonances, or spikes, while the thermal cross section is fairly small. The maximum U^{238} epithermal cross section is roughly four orders of magnitude larger than the corresponding fast and thermal cross sections. This implies a much greater probability (10^4) that an epithermal neutron will be interact with U^{238} , rather than a fast or thermal neutron.

Not all nuclei cross sections exhibit the large energy dependence of the U^{238} cross section, although all neutron cross sections are incident neutron energy dependent. Note the use of the term incident neutron; it refers to a free neutron with potential for interaction(s) with target nuclei. The term distinguishes those neutrons that effectively are input to interactions from those which are effectively output from those interactions.

The presence of a strong resonance tends to depress the neutron flux in the energy band of the resonance. The associated dip in the reaction rate is termed “energy self-shielding.” Doppler broadening of the resonance reduces this energy self-shielding effect. Recalling from Eq. (6) that reaction rate is proportional to cross section and flux, the reduced flux depression results in an increased absorption rate when integrated over the entire resonance.

Cross section resonances have a finite energy width, as opposed to occurring at discrete energies, due to the fact that σ is expressed as a function of neutron energy (or velocity v_n) but is actually dependent upon the relative velocity of the neutron and nucleus $|v_n - v_N|$. Due to the distribution of nuclei velocities from thermal motion, there exists a range of neutron velocities at which the relative velocity $|v_n - v_N|$ matches the resonance. Furthermore, an increase in the temperature of the absorber nuclei will result in a broader distribution of nuclei velocities, v_N , and therefore a broader range of neutron velocities for which $|v_n - v_N|$ matches the resonance. This effectively broadens the resonance peak, and the phenomenon is known as “Doppler broadening” of the resonance. Fig. 3 shows how, for increasing temperatures, the peak of the cross section centered about a particular neutron energy decreases, but the shape broadens, thereby increasing the probability interaction with the spectrum of neutrons. Hence, the net effect of a temperature increase is to increase resonance absorption. This effect has important implications with respect to reactor operation and safety, and will be discussed in a later section.

Moderation and neutron economy in thermal reactors

Since early nuclear engineering efforts, many fission reactor types have been conceived and developed conceptually. The thermal reactor family includes heavy water and light water moderated (and -cooled) reactors and graphite-moderated reactors.

Some of these developments resulted in commercially viable design lines, of which light water reactors (LWRs), both pressurized water reactors (PWRs) and boiling water reactors (BWRs) are the most successful. Because water is being used as coolant and moderator in LWRs, high energy fission neutrons lose their energy (slow down or, in other words, moderate) very quickly. Hence, the great majority of the fissions in the LWR cores is induced by neutrons with energies around 1 eV or lower. Customarily, such low energy neutrons are called thermal neutrons. Subsequently, all LWRs are thermal reactors.

The process whereby a neutron loses energy in a collision with a nucleus is called moderation. When a free neutron loses energy, we say that neutron “slows down” or is moderated. A fission neutron, born with an energy of 2 MeV slows down to below 1 eV while traveling in water, and has thus been moderated by water. The water in an LWR is a “moderator,” in addition to its being the coolant used for heat removal for power conversion to electricity and for safety cooling systems.

For a thermal reactor to be able to be critical, it is not enough to provide sufficient neutron moderation to slow fission neutrons down to thermal energies. It is paramount to complement neutron moderation with sufficiently small parasitic neutron capture probabilities. A neutron capture is considered parasitic if it does not result in a fission event. Therefore, the third necessity is to also enhance neutron-induced fission in the system.

The fast fission neutrons lose their kinetic energy primarily through elastic scattering from moderator nuclei with small mass numbers (except at MeV energies in which inelastic scattering by heavier constituents contributes to the neutron slowing down). Scattering nuclei with small mass numbers cause greater average energy loss per collision and thus thermalize fast neutrons with fewer scatters than do nuclei with large mass numbers. In addition to having a small mass number, a good moderator should be able to provide a high scattering probability and a low absorption probability (to avoid loss of neutrons before they can cause fissions).

The lowest mass moderator is hydrogen; the mass of its nucleus is comparable to that of a neutron. A neutron loses on average half of its kinetic energy upon scattering by a hydrogen nucleus, but hydrogen has a significant absorption cross section, as well. The deuterium atom, at twice the mass of hydrogen, is the next best slowing down agent. Since it already has an extra neutron in its nucleus, it has a very low probability of absorbing a neutron. Deuterium is the best moderator due to it having the lowest neutron absorption cross section thus, heavy water is a much better moderator than light (ordinary) water. Using heavy water, it is possible to sustain the chain reaction using natural uranium. If light water is used as the moderator, as in LWRs, the fuel must then be enriched in ^{235}U .

The carbon atom is also relatively “light,” graphite is relatively inexpensive, and carbon is a relatively weak absorber of neutrons. Accounting for low absorption as one of the key performance metrics for a feasible neutron absorber material, graphite is the 2nd best neutron moderator material outperforming light water. However, since the carbon atom is larger than hydrogen, neutrons have to undergo many more scattering reactions than in water in order to reach thermal energies and this requires a much larger moderator-to-fuel volume ratio than in an LWR. A fission chain reaction can be sustained using natural uranium with graphite moderator, but the graphite needs to be of very high purity. This special type of graphite is called a nuclear-grade graphite. As a result, the core of graphite moderated reactors tend to be large. Heavy water reactor cores also feature a much larger moderator-to-fuel volume ratio than LWR cores. Beryllium is also a good moderator for thermal reactors, but its biological toxicity complicates its use.

A convenient measure of energy in neutron scattering events is logarithmic energy decrement, ξ . It's defined as the average change in the logarithm of neutron energy per collision.

$$\xi = \overline{\ln E_0 - \ln E} = -\ln \overline{E/E_0} \quad (7)$$

By integrating over the angles of scattering to get the average change in energy (meaning $E - E_0$), one gets the following integral equation:

$$\xi = \ln \left(\frac{E_0}{E} \right) = \left(\frac{1}{n} \right) \int_0^\pi -\ln \left(\frac{A^2 + 2A \cos \vartheta + 1}{(1+A)^2} \right) \frac{n}{2} \sin \vartheta d\vartheta \quad (8)$$

Here A is the atomic mass and ϑ is the scattering angle. An additional derivation concludes that for large A only, the solution may be approximated as:

$$\xi = 1 + \frac{(A-1)^2}{2A} \ln \left(\frac{A-1}{A+1} \right) \quad (9)$$

The average loss in the log of the energy per collision is a function of the mass of the target nucleus and is independent of incident neutron energy. Note that for fast neutrons, energy loss will occur on subsequent collisions until thermal energies are achieved. The larger the value of ξ , the fewer the number of collisions required for a fast neutron to achieve thermal equilibrium. This log energy decrement does not completely describe the performance of a material as a moderator. As neutrons interact with moderator nuclei, there also exists a probability for the moderator isotopes to absorb those incident neutrons. Note that the interaction is with the nuclei. So even if the atom that contains the nucleus of interest (with atomic mass A) is bound in some other form, such as U in UO_2 , the A to use in the equation is that of the target nucleus.

When A is small, or is bound in a molecule that can affect the way the nucleus recoils, (such as H in water!!!), then these approximations don't in fact work. However, these data can be both calculated and measured. Thus, these are tabulated and supplied in the [Table 1](#) below.

Table 1 Comparison of moderators.

Material	ξ	#Collisions to thermalize	MSDP	MR
H (in H_2O)	0.930	19	1.425	62
D (in D_2O)	0.510	35	0.177	4800
He	0.427	42	8.0E-6	51
Be	0.207	86	0.154	126
B	0.171	105	0.092	8.0E-4
C (as graphite)	0.158	113	0.061	221
U	0.0083	2192	—	—

The ratio of the macroscopic slowing down power (MSDP), $\xi\Sigma_s$, and the macroscopic absorption cross section, Σ_a , is referred to as the moderating ratio, MR.

Good moderators have large moderating ratios and MSDPs, shown in [Table 1](#).

Due to the fact that it takes more collisions to thermalize in graphite than in other moderators as illustrated in [Table 1](#), graphite-moderated cores, such as helium-cooled high temperature reactors, offer options for nuclear waste management taking advantage of the spectral shift to higher energies. These cores provide favorable environments for high actinide incineration due to increased fractions of higher energy neutrons ([Tsvetkov et al., 2008](#)).

Neutron economy in fast reactors

Alternatively, unlike thermal reactors, other fission reactors provide environments allowing high energy (fast) neutrons to induce fission reactions before they lose their kinetic energy through interactions with various materials on their path. Continuing focusing on the energy range of the neutrons that induce most of the fissions, such fission reactors are called fast reactors. Typically quoted energies of fast neutrons are from about 100 keV to the upper boundary of the fission spectrum that is about 15 MeV. Inherently, fast reactor configurations use material combinations that do not slow neutrons down significantly before they have a chance to be absorbed in the fuel and induce fissions. Liquid metals and gasses as coolants and steels as structural materials are the examples of materials for fast reactors ([Department of Energy, 2021](#)).

[Table 2](#) summarizes generic design characteristics of the contemporary thermal and fast reactors. Physics fundamentals and relevant parameters of fission reactions and their realization in thermal and fast reactors are presented in the subsequent subsections ([Hewitt and Collier, 2000](#); [National Research Council, 2008](#); [Nichols et al., 2008](#)).

In fast reactors, it is desired to utilize fast neutrons before they lose much of their kinetic energies. Hence, in the design of fast reactor systems, not only must parasitic neutron absorption be minimized, but also neutron moderation must be minimized while maximizing neutron-induced fission. The relatively low probability of interaction in the fast neutron energy range is partly compensated by increased fissile inventory in the reactor, partly compensated by the higher density of the fuel material itself, and partly compensated by the increased fissions in fertile materials, such as U^{238} , which is the majority of the actinide content in reactor fuel. Because more of the isotopic content of the fuel either undergoes fission directly, or transmutes to create additional fissionable material, a nuclear fuel cycle economy that uses fast reactors is the most efficient system for the effective utilization of uranium resources, due to the possibility of using the uranium stored in used nuclear fuel to be recycled while producing energy. It is also possible to adopt a strategy of burning (meaning depleting by fission) plutonium along with the uranium stored as tailings from enrichment plants. [Krepel and Losa \(2021\)](#) has additional information of breeding and burning in both thermal and fast reactors.

With these unique features, the energy potential of uranium increases significantly (by a factor of approximately 60) compared to light water reactors (LWRs). In addition, the radioactive wastes containing long-lived actinides created through transmutation become practically insignificant ([OECD-NEA, 2007](#)). For fuel discharged from fast reactors, it is estimated that these long-lived radioactive isotopes, which are responsible for the long term heat load that needs to be managed when the fuel is disposed, contribute less than 0.1% of all the fission products. Hence, a fast spectrum reactor can minimize the mining effort and also reduce nuclear waste storage space and the time required in a repository (by a factor of ~ 1000) to reduce the waste radiotoxicity to the level of the uranium that was originally mined from the ground.

There are several constraints restricting neutron economy characteristics. The configurations must include provisions for controlling fission chain reactions. They must be able to produce utilizable energy outputs that can be harvested and converted into expected energy products. They must be designed to meet financial constraints ([Hamon, 2021](#)).

Notably, lumping fuel into fuel elements increases chances for neutrons that are slowing down to escape parasitic absorption by capture resonances of U^{238} and other actinides. As a result, they thermalize and induce fissions, enhancing the capabilities of heterogeneous configurations versus homogeneous environments to induce and sustain the fission chain reaction. Using heterogeneous configurations is required for establishing a self-sustaining fission process when using natural uranium and moderators with increased parasitic neutron absorption, such as light water. If graphite is used, it is possible to use configurations that mix graphite and fuel together. This is true for all fuel configurations with relatively low fissile content (i.e., low enrichment). However, if fissile

Table 2 Contemporary thermal and fast reactor configurations.

Type	Reactor	Fuel	Moderator	Coolant
Thermal	PWR	UO_2 , 3–4.5% U^{235}	H_2O	H_2O
	BWR	UO_2 , 3–4.5% U^{235}	H_2O	H_2O
	CANDU	UO_2 , 0.7% U^{235}	D_2O	D_2O or H_2O
	AGR	UO_2 , 3–4% U^{235}	Graphite	CO_2
	HTGR	UO_2 , 6–10% U^{235}	Graphite	He
Fast	SFR	$(U,Pu)O_2$, U, UN, 10–20% fissile content	None	Sodium

content is relatively high, with increased fractions of U^{235} in the fresh fuel composition, for example, the design approach is the opposite. It becomes more favorable for enhanced neutron economy to mix fuel and moderator together into homogeneous configurations. This increases the chance for neutrons to interact with the fissile nuclei.

Neutron-induced fission chain reactions and neutron multiplication

The multiplication factor is defined as the ratio of the number of fissions in any one generation to the number of fissions in the immediately preceding generation, as in (10). When this factor is exactly equal to unity the number of fissions in each succeeding generation is, on average, constant, and a chain reaction initiated in the system will continue at a constant rate. A system in such a state is called “critical.” In a critical system, the neutron generation rate and neutron loss rate are equal. Neutrons can be lost via absorption in the system constituents or leakage out of the system. If the neutron production rate is larger (smaller) than the neutron loss rate, the system is “super (sub)-critical” and its fission rate increases (decreases) with time (Lynn, 2004).

$$k \equiv \frac{\text{number of neutrons in one generation}}{\text{number of neutrons in preceding generation}} \quad (10)$$

This so called “life cycle” definition leads to a conceptually simple evaluation of k , illustrated in Fig. 3. We can represent the number of neutrons in one generation as a function of the number in the preceding generation by defining the probabilities associated with the various processes involved for a fission neutron to eventually cause subsequent fission neutrons to be born. For thermal reactors, this relationship can be expressed as the product of the following terms:

1. The fast non-leakage probability, $P_{FNL} \equiv$ the probability that a fast neutron will not leak out of the core before slowing down.
2. The resonance escape probability, $p \equiv$ the probability that a neutron will not be absorbed during its slowing down process.
3. The thermal non-leakage probability, $P_{TNL} \equiv$ the probability that a thermal neutron will not leak out of the core.
4. The thermal utilization factor, $f \equiv$ the probability that if a thermal neutron is absorbed, it is absorbed in fuel:

$$f = \frac{\Sigma_a^{\text{Fuel}}}{\Sigma_a} \quad (11)$$

5. The reproduction factor, $\eta \equiv$ the number of neutrons produced by thermal neutron induced fission per neutron absorbed in the fuel.
6. The fast fission factor, ϵ a factor which characterizes the additional neutrons produced by fast neutron induced fissions:

$$\epsilon \equiv \frac{\text{total number of fission neutrons (fast and thermal)}}{\text{number of neutrons from thermal fission}} \quad (12)$$

Hence,

$$k = \eta f p \epsilon P_{FNL} P_{TNL} \quad (13)$$

which is known as the six factor formula. By this definition, k is sometimes referred to as the “effective” multiplication constant, k_{eff} , since it characterizes a finite system. In nuclear theory, k_{eff} is the parameter that models how far away from criticality a reactor is, given a set of fuel properties. It may be thought of as a variable used to artificially modify fuel properties to achieve a critical reactor. When k_{eff} is equal to 1.0000, the reactor would be critical with a given flux distribution and fixed fission rate. The portion of this multiplication constant that is not associated with the finite core is the “infinite” multiplication factor, k_{∞} , wherein:

$$k_{\text{eff}} = k_{\infty} P_{FNL} P_{TNL} \quad (14)$$

Fig. 4 schematically demonstrates the fission “life cycle” for 1000 fast fission neutrons within a thermal critical core (i.e., $k_{\text{eff}} = 1.0$), including the slowing down of neutrons, the processes whereby neutrons can be lost to leakage and the probability of inducing subsequent fission.

In order to maintain a self-sustained chain reaction in a reactor, a balance must be established between the rate at which neutrons are produced in the core and the rate at which they disappear. Neutrons disappear in two ways; they either leak from the surface of the core or are absorbed within its interior. The rates at which neutron leakage and absorption occur are governed by the size and composition of the core. Operational control of the process is through increasing or decreasing the neutron capture rates and sometimes also leakage rates. Control materials are moved into, or out of, the core as required to achieve this goal.

If we assume an infinite nuclear fuel system, and therefore assume the probabilities of fast non-leakage, P_{FNL} , and thermal non-leakage, P_{TNL} , are 1.0 (i.e., no fast or thermal leakage), Eq. (14) reduces to what is essentially a property of the material component of the thermal reactor:

$$k_{\infty} = \eta f p \epsilon \quad (15)$$

Fig. 4 Example of life cycle of 1000 neutrons.

Reactivity effects

“Reactivity” is a measure of the deviation of the multiplication factor from 1.0000, and is defined as:

$$\rho = \frac{k_{eff} - 1}{k_{eff}} \quad (16)$$

The symbol ρ is commonly used to express reactivity, but this is not to be confused with mass density, which, unfortunately, uses the same symbol in nuclear engineering texts. It is also common practice to express $(k_{eff} - 1)$ as Δk and reactivity as $\Delta k/k$. In the following discussion, major reactivity effects in a BWR will be considered and the nature of the impact of these effects on k_{eff} will be discussed in terms of the 6-factor formula. Since actual changes in reactor conditions involve numerous, and often subtle, mechanisms and interactions, the validity of this sort of qualitative discussion is limited to first order effects.

U^{235} depletion

Depletion of U^{235} through burnup (that is, through fission), results in a decrease in k_{eff} due to a decreased thermal utilization factor, f :

$$f = \frac{\Sigma_a^{Fuel}}{\Sigma_a} \quad (17)$$

As the number of fissile atoms of U^{235} decrease (due to fission and capture), the macroscopic cross section, Σ_a^{Fuel} must likewise decrease, thereby reducing the thermal utilization factor.

Control density

The dominant effect of control insertion is the addition of B^{10} , which has a very large thermal neutron cross-section for the absorption reaction:

The addition of a strong absorber (B^{10}) increases the problem total macroscopic absorption cross section, thereby decreasing the thermal utilization factor, f , and therefore k_{eff} . Other neutron poison materials, such as AgInCd or Hf, are also used for reactivity control purposes. Different reactor types add a control material in different ways (Young, 2021). The most common method of inserting at least some neutron poisons into a reactor core is through the use of control rods (in the case of PWRs) or control blades (in the case of BWRs). For PWRs, though, the main reactivity control through the cycle is the use of soluble boron directly in the coolant (the concentration of the boron is adjusted throughout the cycle). Control rods are used there only for shutdown and for some power shaping. For BWRs, the main control mechanism is the use of control rods. Soluble boron injection is available for emergency shutdown purposes (Brown, 2021).

Moderator density or displacement

A secondary consideration in the insertion of control rods or blades in a core is that these devices occupy some space. That space was previously occupied by moderator. In general, light water reactors operate in an undermoderated state, meaning that removing moderator reduces the reactivity. So the insertion of control rods “inserts negative reactivity” both by introducing a thermal neutron absorber and by removing moderator from the core.

The same effect of lowering moderator density is also achieved by temperature increases in a PWR (at the same system pressure), or additional voiding of the water in a BWR. Such moderator reactivity feedback is an inherent aspect of the reactor’s response to abnormal events to return the reactor to a lower power state.

Burnable absorbers

Neutron absorbers that deplete (or “burn”) relatively quickly are commonly used in reactors to compensate for excess reactivity early in the cycle, and are referred to as “burnable poisons.” Gadolinium is used in BWR fuel and some PWR fuel for this purpose in the form of an oxide (Gd_2O_3) which is mixed in with the UO_2 in selected fuel rods at selected axial locations. Thin coatings of ZrB_2 within the fuel rods may also serve this same purpose. Burnable absorbers decrease k_{eff} in a manner similar to B^{10} , by decreasing the thermal utilization factor, f . As the fissile fuel concentration depletes with burnup, so does the concentration of the burnable absorbers so there is a reduced need to use control rods for long-term reactivity control.

Fuel temperature/Doppler effect

The resonance escape probability, p , may be expressed as the inverse of an exponential of the ratio of the resonance integral for the fuel to the scattering cross sections of the fuel, structure and moderators.

The resonance integral is essentially a method of integrating the absorption cross section of the fuel material in the with neutron energy in the epithermal region (the energy range with hash in Fig. 2). This is dependent on the mass density of the fuel material and the size (diameter) of the fuel rods. The fuel’s macroscopic absorption cross section in the resonance region is dominated for most reactors by the U^{238} , since it is the vast majority of the nuclei in the fuel material. Importantly, resonance cross sections, and therefore the resonance integral, are affected by temperature.

Because of increased resonance absorption arising from the Doppler broadening effect described earlier, the effective resonance integral will increase with increasing fuel temperature. Experimental measurements are represented by.

$$I(T) = I(300K) \left[1 + \beta \left(\sqrt{T} - \sqrt{300} \right) \right] \quad (19)$$

where $I(T)$ is the effective resonance integral at temperature T (Kelvin) and $I(300 K)$ is the integral at 300 K. β is a constant that depends on the nature of the fuel and on the radius of the fuel rod in a heterogeneous system. Therefore, as the temperature of the fuel increases, the resonance integral increases, which decreases the resonance escape probability. Through this mathematical model, a fuel temperature increase results in a lower neutron multiplication since the absorptions in U^{238} reduces the fraction of fission neutrons that reach thermal energies to cause fission, which is a negative reactivity. It is this Doppler effect that, in the

event of a power increase, and subsequent fuel temperature increase, results in an inherent prompt negative reactivity feedback to return the reactor to a normal state.

Plutonium buildup

When U^{238} absorbs a neutron, the resulting atom undergoes the following sequence of decays:

Pu^{239} is also a fissile isotope and therefore, it may then fission or undergo successive neutron captures to produce Pu^{241} , which is also fissile. In a reactor, as fuel burnup increases, parasitic neutron capture by the large concentration of U^{238} in the fuel results in plutonium quickly becoming a significant, and eventually dominant, contributor to the chain reaction. This is due to increased thermal utilization resulting from an increase in the macroscopic fission cross-section.

Production of plutonium is due primarily to resonance absorption, while the process that removes fissile material (i.e., fission) occurs primarily at thermal energies. As a consequence of this, the ratio of fissile Pu buildup to fissile U and Pu depletion, also called "conversion ratio," is strongly dependent upon the neutron energy spectrum. Any factor that tends to "harden the spectrum" (increase the fast flux/thermal flux ratio) will result in more buildup of Pu^{239} and Pu^{241} and less burnout of all fissile isotopes.

Reactor physics

Reactor physics is a mathematical means to determine the relationship between the characteristics of the reactor material (through expressions for k , as above in the four-factor formula of Eq. 15) and the finite geometry and arrangement, which essentially determines the fast and thermal non-leakage probabilities in the six factor formula of Eq. (14). These will be dependent on the total neutron flux, Φ , which is defined as the number of neutrons crossing a unit area per second. Reaction rates, such as the fission rate, and therefore reactor power, are proportional to the neutron flux.

Consider an arbitrary volume V within a medium containing neutrons. As time goes on, the number of neutrons in V may change if there is a net flow of neutrons in or out of V , if some neutrons are absorbed within V and if some neutrons are created within V . The equation of continuity is the mathematical statement of the obvious fact that all neutrons can be accounted for. This is summarized by the following:

$$\left[\begin{array}{c} \text{rate of change in} \\ \text{number of neutrons} \end{array} \right] = \left[\begin{array}{c} \text{rate of production} \\ \text{of neutrons} \end{array} \right] - \left[\begin{array}{c} \text{rate of absorption} \\ \text{of neutrons} \end{array} \right] - \left[\begin{array}{c} \text{rate of leakage} \\ \text{of neutrons out of } V \end{array} \right] \quad (21)$$

By invoking Fick's law to relate the rate of leakage from the volume to a proportionality constant, called the diffusion coefficient, D , and the gradient of the flux, the change in the neutron population (which is the flux divided by the velocity of the neutrons) is given by:

$$\frac{1}{v} \frac{d\phi}{dt} = k_{\infty} \Sigma_a \phi - \Sigma_a \phi + D \nabla^2 \phi \quad (22)$$

For the purposes of this explanation, we are only interested in the steady-state behavior of the neutron flux, so that the left hand side is set to zero. Upon rearrangement, Eq. (22) then becomes the homogenous, one energy group, reactor equation:

$$\nabla^2 \phi + \frac{(k_{\infty} - 1) \Sigma_a}{D} \phi = 0 \quad (23)$$

Solutions to Eq. (23) are well known eigenfunction solutions and the form of that solution is dependent on the nature of the geometry being analyzed (for instance, cylinder, sphere, parallelepiped, shown in Fig. 5) and the boundary conditions imposed.

Consider the five geometries in Fig. 5. These distinct geometries have distinct forms for their solutions. As an example, take the infinite slab geometry. This will have boundary conditions such that the flux is zero at the edges. Thus,

$$\phi\left(\frac{a}{2}\right) = \phi\left(-\frac{a}{2}\right) = 0 \quad (24)$$

It may also be noted that because of the symmetry of the problem, there can be no net flow of neutrons at the center of the slab. Since the current density is proportional to the spatial derivative of ϕ , we have:

$$\frac{d\phi}{dx} = 0, \text{ at } x = 0. \quad (25)$$

The general solution to (23) in one Cartesian dimension, with the above boundary condition is:

$$\phi(x) = C_1 \cos Bx \quad (26)$$

Fig. 5 Reactor core geometries. Reactor geometries: (a) the slab reactor; (b) the spherical reactor; (c) the infinite cylindrical reactor; (d) the parallelepiped reactor; (e) the finite cylindrical reactor.

Next, introducing the boundary condition given by Eq. (24) gives.

$$\phi\left(\frac{a}{2}\right) = C_1 \cos\left(\frac{Ba}{2}\right) = 0 \quad (27)$$

The non-trivial solution then demands that:

$$B_n = \frac{n\pi}{a}, n = 1, 3, 5 \dots \quad (28)$$

The various constants B_n are known as the eigenvalues and the corresponding functions, $\cos(B_n x)$, are called eigenfunctions. It can be shown that if the reactor were not critical, the flux would be the sum of all eigenfunctions, each multiplied by a function that depends on time. However, if the reactor is critical, all of these functions except the first die out quickly and the flux assumes the steady-state shape of the first eigenfunctions or fundamental, namely,

$$\phi(x) = C_1 \cos(B_1 x) = C_1 \cos\left(\frac{\pi x}{a}\right) \quad (29)$$

Note that the value of “ a ” has not yet been established. The reason is that, while the form has been established, no conditions on the reactor power have been imposed. To determine the magnitude of the flux, the power level needs to be considered as related to the flux by the relationship:

$$P = E_f \Sigma_f \int_V \phi(\mathbf{r}) d\mathbf{r} = E_f \Sigma_f \int_{-a/2}^{a/2} \phi(x) dx \quad (30)$$

where E_f = the recoverable energy per fission (about 193 MeV, or 3.1×10^{-11} J). Performing the integration for the slab geometry, we have the final form of the one-group bare reactor equation:

$$\phi(x) = \frac{\pi P}{2aE_f \Sigma_f} \cos\left(\frac{\pi x}{a}\right) \quad (31)$$

Other geometries are handled, in principle, in a likewise manner. See Table 3 for the parameters associated with the various reactor geometries. Note that this relationship holds for a “bare” reactor, meaning that no reflector around the outside (designed to reflect neutrons back into the reactor) has been included. For the reflected reactor, the equations would be modified through imposition of different boundary conditions.

Present day reactor physics design and analysis is using a much more sophisticated physics and mathematics models and computational tools than described above. For more details see Walters (2021) and Fiorina (2021).

Physics-driven design considerations for thermal and fast reactors

The nuclear design of a reactor involves defining the nuclear environment that will exist inside the reactor core. This phase of design work has a great bearing on thermal-hydraulic and mechanical analyses; hence, close coordination with these activities must be

Table 3 Bucklings and fluxes for critical bare reactors.

Geometry	Dimensions	Buckling	Flux	C_1	ϕ_{max}/ϕ_{avg}
Infinite slab	a	$\left(\frac{\pi}{a}\right)^2$	$C_1 \cos\left(\frac{\pi x}{a}\right)$	$\frac{1.57P}{aE_R \Sigma_f}$	1.57
Rectangular parallelepiped	$a \times b \times c$	$\left(\frac{\pi}{a}\right)^2 + \left(\frac{\pi}{b}\right)^2 + \left(\frac{\pi}{c}\right)^2$	$C_1 \cos\left(\frac{\pi x}{a}\right) \cos\left(\frac{\pi y}{b}\right) \cos\left(\frac{\pi z}{c}\right)$	$\frac{3.87P}{VE_R \Sigma_f}$	3.88
Infinite cylinder	Radius R	$\left(\frac{2.405}{R}\right)^2$	$C_1 J_0\left(\frac{2.405r}{R}\right)$	$\frac{0.738P}{R^2 E_R \Sigma_f}$	2.32
Finite cylinder	Radius R Height H	$\left(\frac{2.405}{R}\right)^2 + \left(\frac{\pi}{H}\right)^2$	$C_1 J_0\left(\frac{2.405r}{R}\right) \cos\left(\frac{\pi z}{H}\right)$	$\frac{3.63P}{VE_R \Sigma_f}$	3.64
Sphere	Radius R	$\left(\frac{\pi}{R}\right)^2$	$C_1 \frac{1}{r} \sin\left(\frac{\pi r}{R}\right)$	$\frac{P}{4R^2 E_R \Sigma_f}$	3.29

maintained (Fiorina, 2021). Safety and control requirements are closely tied to the nuclear design effort and must be considered for all phases of the fuel cycle. Space-dependent power distributions are needed in order to determine peak powers and temperatures for thermal-hydraulic and structural analyses (Walters, 2021). Reactor physics (also referred to as “neutronics”) calculations are needed to obtain, among other design parameters, the optimal moderator-to-fuel volume ratio, fissile fraction (enrichment), fixed and burnable absorber inventories required by the core design, optimal management of the fuel within the core (also referred to as “in-core fuel-management”), required reactor control systems (for both reactivity control and power shaping), attainable fuel burnup (amount of energy extracted per unit fuel weight), composition and radioactivity of the discharged fuel, reactivity coefficient due to change in components temperature and density, as well as the transient response of the reactor core during upset conditions (Martin, 2021).

The core of a fast reactor is smaller than that of a thermal reactor of comparable power. A thermal reactor is optimized at some particular fuel-to-moderator ratio, and any core smaller than optimum represents a less economic configuration. At optimum moderation, either the increase of moderator or the removal of moderator (for instance, due to steam formation in boiling), results in a decrease in the k_∞ of the core.

For a fast reactor, no moderator is needed; in fact, a moderator is normally excluded by design in order to maintain a fast spectrum. Since these reactors do not utilize thermal neutrons, the balance is optimized through the neutron leakage of the core. Whereas for thermal reactors one of the objectives of the reactor physics design is to find the optimal moderator-to-fuel volume ratio, for fast reactors the corresponding design objectives is to maximize the fuel volume fraction and minimize the coolant volume fraction. The higher is the amount of uranium and plutonium per unit core volume, the harder will be the neutron spectrum (higher will be the average energy of the neutrons) and the better will be the neutron economy more excess neutrons available for breeding or for incinerating nuclear waste (Tsvetkov, 2021). Because of the incentive to minimize the specific fissile inventory in the fast reactor, the spacing between fuel rods is different than in a light water reactor so that the pitch between rods is minimized in the lattice array of rods that makes up a fuel assembly (Young, 2021). A triangular lattice arrangement of the fuel rods intrinsically allows a higher fuel volume fraction than the square lattice typically used in LWRs. A triangular lattice arrangement intrinsically allows a higher fuel volume fraction than a square lattice. The higher fuel volume fraction minimizes fissile loading mainly by reducing reactor leakage. Hence, the triangular lattice or hexagonal structure has been universally selected for fast reactor design.

Nuclear data

The common approach of representing energy dependence of neutron-nucleus interactions consists of discretizing the energy dependence in a number of energy groups. During the fission reactions neutrons are emitted with an average energy of approximately 2 MeV. Neutron numbers are negligibly small above 10–15 MeV, making the maximum energy of interest in most nuclear fission reactors to be of about 15 MeV. Neutrons are then slowed down to much lower energies by collisions with the reactor components. The energy-dependent neutron spectrum in a reactor takes into account probabilities of absorption events, slowing down by elastic and inelastic collisions, and of leakage out of the system.

It is important to determine the rate at which various types of neutron-nuclear reactions occur within the reactor (Lucius and Marable, 1979). Because of the wide range of neutron energies and the very strong energy dependence of some neutron-nucleus cross-sections, this number of energy groups should be sufficiently high to capture necessary spectral details. Since the energy dependence of the cross-sections within these groups cannot be neglected, group average cross-sections have to be produced. The actual numbers of energy groups to be used in multigroup calculations vary according to the complexity of the calculations being performed and the accuracy desired.

All nuclear reactor calculations rely on the knowledge of the various relevant neutron-nuclear cross sections. The complicated dependence of such cross sections on neutron energy and angle of incidence combined with the large number of nuclides involved in nuclear reactor analysis implies that large databases are needed for storing nuclear data compilations. Such compilations have been accumulated over the past few decades from both experimental programs and theoretical calculations.

Nuclear cross section professionals have decided to consolidate and standardize all of the cross section information into the Evaluated Nuclear Data Files (ENDF) (Chadwick et al., 2006). The ENDF system contains both neutron and photon cross-section data. These data are stored in four Internet-accessible nuclear reaction databases:

- EXFOR, alias CSISRS (Cross Section Information Storage and Retrieval System), is a database containing experimental data. This data set contains unevaluated raw data from experimental measurements. The data presently included in the EXFOR database include compilations of experimental neutron-induced reaction data, charged-particle induced reaction data, and photon-induced reaction data. It covers more than 18,600 experiments and spans nearly all of neutron induced reactions experimental works worldwide.
- ENDF (Evaluated Nuclear (reaction) Data File) databases:
- ENDF/A data set contains both complete and incomplete sets of nuclear data as soon as they become available. For each isotope there may be more than one data set for a particular reaction, or there may be none at all for certain reactions of interest.
- ENDF/B is the main nuclear reaction database containing evaluated (recommended) data from the ENDF/B library (also JEFF, JENDL, BROND, ROSFOND and CENDL). It provides data in the ENDF format, covering all nuclides of practical relevance (393 in total) for neutrons up to 20 MeV and partly up to 150 MeV. It serves as principal input for neutronics calculations, including nuclear reactor design, national security, accelerators, criticality safety, shielding, radiation protection and detector simulations. The ENDF/B data set contains only complete, evaluated sets of nuclear data presented in a form that can be efficiently accessed and processed.
- RIPL (Reference Input Parameter Library) database contains input parameters for theoretical calculations of nuclear reactions.
- SIGMA (ENDF retrieval and plotting) database contains evaluated (recommended) nuclear reaction and decay data from ENDF/B, JEFF, JENDL, CENDL, ROSFOND libraries.

In addition to the nuclear data retrieval systems, there are two Internet-accessible bibliographical databases:

- CINDA (Computer Index of Nuclear (reaction) Data) database contains bibliographical neutron induced reaction information, including experimental, theoretical and evaluation works. It contains references to 275,000 reactions from 55,000 works worldwide.
- NSR (Nuclear Science References) database contains bibliographical nuclear physics information including more than 200,000 nuclear science articles, indexed according to content. It spans for 100 years of research, and currently covers 80 journals with about 3800 new articles added each year worldwide.

The ENDF data representation format and the ENDF/B data set are the accepted data presentation standard and the reference data set that are used worldwide for nuclear reactor data representation and for reactor analysis applications. Control over the ENDF formats has been retained by the US Cross Section Evaluation Working Group (CSEWG). The format specifications are published through the National Nuclear Data Center at the Brookhaven National Laboratory.

Glossary

Anticipated operational occurrences Anticipated operational occurrences mean those conditions of normal operation which are expected to occur one or more times during the life of the nuclear power unit and include but are not limited to loss of power to all recirculation pumps, tripping of the turbine generator set, isolation of the main condenser, and loss of all offsite power [10 CFR 50 Appendix A].

Loss-of-coolant accidents Loss-of-coolant accidents mean those postulated accidents that result from the loss of reactor coolant at a rate in excess of the capability of the reactor coolant makeup system from breaks in the reactor coolant pressure boundary, up to and including a break equivalent in size to the double-ended rupture of the largest pipe of the reactor coolant system [10 CFR 50 Appendix A].

Reactivity A term expressing the departure of a reactor system from criticality; that is, of Keff value from 1 (1-Keff-1). A positive reactivity addition indicates a move toward supercriticality (power increase). A negative reactivity addition indicates a move toward subcriticality (power decrease).

Safety-related structures, systems and components Means those structures, systems and components that are relied upon to remain functional during and following design basis events to assure: (1) The integrity of the reactor coolant pressure boundary; (2) The capability to shut down the reactor and maintain it in a safe shutdown condition; or (3) The capability to prevent or mitigate the consequences of accidents which could result in potential offsite exposures comparable to the applicable guideline exposures [10 CFR 50.2].

Single failure A single failure means an occurrence which results in the loss of capability of a component to perform its intended safety functions. Multiple failures resulting from a single occurrence are considered to be a single failure. Fluid and electric systems are considered to be designed against an assumed single failure if neither (1) a single failure of any active component (assuming passive components function properly) nor (2) a single failure of a passive component (assuming active components function properly), results in a loss of the capability of the system to perform its safety functions [10 CFR 50 Appendix A].

Introduction

When designing a nuclear power plant, the plant designer has significant flexibility in choosing how the plant is configured and operated. General design criteria (GDCs) provide high level regulatory safety requirements for light water reactors that must be satisfied. The reactor designer establishes the specific plant/system configuration that results in compliance with the GDCs. In addition to regulatory requirements, utility groups in the United States and Europe have developed their own detailed design and operational requirements for new plant designs that expand on local regulatory requirements. Both safety and operational design requirements are discussed.

Utility design requirements

In the United States, the Electric Power Research Institute (EPRI) has developed the utility requirements document (URD) (EPRI, 2014) in cooperation with utilities and reactor vendors. The URD presents a clear, complete statement of Utility expectations for the design and operation of advanced light water reactors that is divided into three tiers. Tier 0 presents an executive summary of the URD. Tier 1 presents policy and top-tier design requirements, which also includes bounding environmental and seismic design requirements that will conservatively apply to most potential sites for new US nuclear power plants. Tier 2 contains thousands of specific requirements covering all major aspects of the plant design. Table 1 presents the list of chapter titles that comprise URD Tier 2.

A group of European utilities has developed a comparable document known as the European Utility Requirements (EUR) Document (EUR Organization, 2016). The EUR Document consists of a comprehensive nuclear power plant specification written by a group of the potential investors in electricity generation in Europe. The EUR document is structured into four volumes. Volume 1, Main policies and top-tier requirements, defines the major design objectives and presents the main policies that are implemented in the EUR document. Volume 2, Generic nuclear island requirements, contains all the generic requirements and preferences of the EUR utilities for the nuclear island. Volume 3, Specific nuclear island requirements, is prepared by a reactor vendor to describe how their plant design addresses the generic requirements in Volume 2. Volume 4, Power generation plant requirements, contains the generic requirements related to the power generation plant (i.e., turbine-generator systems). Additional background information on the development of the EUR document can be found in Roche (2001).

Some of the operational considerations found in the URD and the EUR include desired load following capabilities and operating design margin to Technical Specification limits for operation of the reactor core throughout a fuel cycle. In addition, while most

operating plants were originally designed for an operating life of 40 years, utility customers now expect new plants to be designed for an operating life of at least 60–80 years.

Regulatory requirements

The US nuclear regulatory process includes mandatory regulations (Bley, 2021; Bley and Malsch, 2021) which primarily appear in 10 CFR 50 and its various subparts, as well as guidance documents that include regulatory guides and the Standard Review Plan. The classification of structures, systems and components is an important part of regulatory guidance, as are requirements related to the defense in depth and diversity of the overall plant design and its control systems. An overview of these topics is provided below.

General design criteria

Appendix A of 10 CFR 50 defines a set of top-level requirements for light water reactors that are known as the General Design Criteria (GDCs). These General Design Criteria establish minimum requirements for the principal design criteria for water-cooled nuclear power plants. The General Design Criteria are also considered to be generally applicable to other types of nuclear power units and are intended to provide guidance in establishing the principal design criteria for such other units.

The GDCs are divided into six categories: Overall Requirements (GDCs 1–5), Protection by Multiple Fission Product Barriers (GDCs 10–19), Protection and Reactivity Control Systems (GDCs 20–29), Fluid Systems (GDCs 30–46), Reactor Containment (GDCs 50–57) and Fuel and Reactivity Control (GDCs 60–64). See Table 2 for a complete list of GDC requirements.

General Design Criterion 1 requires that structures, systems, and components important to safety be designed, fabricated, erected, and tested to quality standards commensurate with the importance of the safety functions to be performed. It also requires a quality assurance program to be established and implemented in order to provide adequate assurance that these structures, systems and components will satisfactorily perform their safety functions.

GDC 2 addresses the design basis for protection against natural phenomena, such as earthquakes, tornadoes, hurricanes and floods. When selecting a proposed site for a nuclear power plant, the applicant for a permit must provide detailed assessments of the most severe external events and environmental conditions that might be experienced during the plant lifetime. Chapter 2 of the standard review plan (NUREG-0800) provides detailed guidance to the applicant on siting requirements.

GDCs 12 and 13 address instrumentation and controls for suppressing reactor power oscillations and for maintaining the reactor within its design limits during normal operation, anticipated operational occurrences and accident conditions to ensure the integrity of the reactor core, the reactor coolant pressure boundary, the containment and its associated systems.

Other GDCs address performance requirements for plant safety systems that provide primary safety functions during loss-of-coolant accident (LOCA) and other design basis accident events. The primary safety functions referred to in the GDCs include core cooling, containment heat removal and maintaining containment integrity to prevent releases of radioactive materials.

Regulatory guides and standard review plan

The NRC has issued over 200 regulatory guides that address what the nuclear regulatory commission (NRC) considers to be appropriate guidance for addressing various design issues in nuclear power plants. The application of these regulatory guides to a specific plant design is defined by NUREG-0800, “Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants: LWR Edition.” NUREG-0800 (US NRC, n.d.) consists of several hundred individual sections, each under separate revision control, which correspond to the table of contents for a plant safety analysis report (SAR).

Table 2 General design criteria.

	<i>Criteria</i>	<i>Number</i>
I. Overall requirements:	Quality standards and records	1
	Design bases for protection against natural phenomena	2
	Fire protection	3
	Environmental and dynamic effects design bases	4
	Sharing of structures, systems, and components	5
II. Protection by multiple fission product barriers:	Reactor design	10
	Reactor inherent protection	11
	Suppression of reactor power oscillations	12
	Instrumentation and control	13
	Reactor coolant pressure boundary	14
	Reactor coolant system design	15
	Containment design	16
	Electric power systems	17
	Inspection and testing of electric power systems	18
	Control room	19
	Protection system functions	20
III. Protection and reactivity control systems:	Protection system reliability and testability	21
	Protection system independence	22
	Protection system failure modes	23
	Separation of protection and control systems	24
	Protection system requirements for reactivity control malfunctions	25
	Reactivity control system redundancy and capability	26
	Combined reactivity control systems capability	27
	Reactivity limits	28
	Protection against anticipated operational occurrences	29
	Quality of reactor coolant pressure boundary	30
	Fracture prevention of reactor coolant pressure boundary	31
IV. Fluid systems:	Inspection of reactor coolant pressure boundary	32
	Reactor coolant makeup	33
	Residual heat removal	34
	Emergency core cooling	35
	Inspection of emergency core cooling system	36
	Testing of emergency core cooling system	37
	Containment heat removal	38
	Inspection of containment heat removal system	39
	Testing of containment heat removal system	40
	Containment atmosphere cleanup	41
	Inspection of containment atmosphere cleanup systems	42
	Testing of containment atmosphere cleanup systems	43
	Cooling water	44
	Inspection of cooling water system	45
	Testing of cooling water system	46
	Containment design basis	50
	Fracture prevention of containment pressure boundary	51
V. Reactor containment:	Capability for containment leakage rate testing	52
	Provisions for containment testing and inspection	53
	Systems penetrating containment	54
	Reactor coolant pressure boundary penetrating containment	55
	Primary containment isolation	56
VI. Fuel and radioactivity control:	Closed systems isolation valves	57
	Control of releases of radioactive materials to the environment	60
	Fuel storage and handling and radioactivity control	61
	Prevention of criticality in fuel storage and handling	62
	Monitoring fuel and waste storage	63
	Monitoring radioactivity releases	64

Each standard review plan (SRP) section provides background information on the topic being addressed in the corresponding SAR section, defines applicable regulations and regulatory guides to be considered, and provides direction to the NRC reviewer regarding what to look for in this SAR section before approving the section. Some SRP sections make it mandatory to apply specific regulatory guides, while other SRP sections make recommendations to apply specific regulatory guides. When recommendations are

provided, the reactor designer may propose an alternative approach to addressing this topic provided it can be demonstrated that the alternative approach provides a comparable level of protection. Each SRP section also identifies important industry codes and standards that need to be considered during the design process.

The revisions of SRP sections and Regulatory Guides that apply to a plant are generally the most recent ones available 6 months prior to the licensing submittal that references them. Subsequent revisions of the SRP sections and Regulatory Guides do not automatically apply. If a plant owner chooses to apply newer revisions then additional NRC review will likely be required.

Classification of structures, systems and components

Several different types of classifications are applied to the structures, systems and components (SSCs) of a nuclear power plant.

Seismic classification

The SSCs of a nuclear power plant that are designated as Seismic Category I must be designed to withstand the effects of the SSE and remain functional. The pertinent quality assurance requirements of Appendix B to 10 CFR Part 50 shall apply to all activities affecting the safety-related functions of seismic Category I SSCs. Section C of RG 1.29 ([US NRC, 2016b](#)) provides a detailed list of the types of SSCs that are required to be designated as Seismic Category I.

Structures, systems and components that perform no safety-related function, but whose structural failure or interaction could degrade the functioning of a Seismic Category I item to an unacceptable level of safety or could result in incapacitating injury to occupants of the main control room, are designated Seismic Category II. These items are structurally designed to withstand the effects of an SSE.

SSCs in radioactive waste management systems are required to be designed in accordance with requirements from RG 1.143 ([US NRC, 2001](#)). Most other SSCs that aren't designated as either Seismic Category I or II are only required to comply with seismic requirements from the International Building Code (IBC) or corresponding local building codes.

Quality group

Quality Group A corresponds to the category of components that must meet the requirements for Class 1 components in Section III of the American Society of Mechanical Engineers (ASME) boiler and pressure vessel (BPV) code. This category is limited to components that are part of the reactor coolant pressure boundary, except for the portions excluded by 10 CFR 50.55a(c)(2) that are included in Quality Group B below. This exclusion applies to components whose failure would not prevent the reactor from being shut down and cooled down in an orderly fashion with normal makeup and components that are or can be isolated from the reactor coolant system by two valves in series (with automatic closure of open valves).

The Quality Group B standards given in Table 1 of RG 1.26 ([US NRC, 2017](#)) should be applied to water- and steam-containing pressure vessels, heat exchangers (other than turbines and condensers), storage tanks, piping, pumps, and valves that are either (1) part of the reactor coolant pressure boundary but excluded from the requirements of 10 CFR 50.55a(c)(1) for reactor coolant pressure boundary components pursuant to paragraph (c)(2) of that section (as mentioned above in the section on Quality Group A), or (2) not part of the reactor coolant pressure boundary but part of the following:

- (a) systems or portions of systems important to safety that are designed for (i) emergency core cooling, (ii) post-accident containment heat removal, or (iii) post-accident fission product removal;
- (b) systems or portions of systems important to safety that are designed for (i) reactor shutdown or (ii) residual heat removal;
- (c) those portions of the steam systems of boiling-water reactors extending from the outermost containment isolation valve up to but not including the turbine stop and bypass valves, and connected piping up to and including the first valve that is either normally closed or capable of automatic closure during all modes of normal reactor operation
- (d) those portions of the steam and feedwater systems of pressurized-water reactors extending from and including the secondary side of steam generators up to and including the outermost containment isolation valves, and connected piping up to and including the first valve (including a safety or relief valve) that is either normally closed or capable of automatic closure during all modes of normal reactor operation; and
- (e) systems or portions of systems that are connected to the reactor coolant pressure boundary and are not capable of being isolated from the boundary during all modes of normal reactor operation by two valves, each of which is either normally closed or capable of automatic closure.

The Quality Group C standards given in Table 1 of RG 1.26 should be applied to water-, steam-, and radioactive-waste-containing pressure vessels; heat exchangers (other than turbines and condensers); storage tanks; piping; pumps; and valves that are not part of the reactor coolant pressure boundary or included in Quality Group B but part of the following:

- (a) cooling water and auxiliary feedwater systems or portions of those systems important to safety that are designed for (i) emergency core cooling, (ii) post-accident containment heat removal, (iii) post-accident containment atmosphere cleanup, or (iv) residual heat removal from the reactor and from the spent fuel storage pool (including primary and secondary cooling systems), although Quality Group B includes portions of those systems that are required for their safety functions and that (i) do not operate during any mode of normal reactor operation and (ii) cannot be tested adequately;

- (b) cooling water and seal water systems or portions of those systems important to safety that are designed for the functioning of components and systems important to safety, such as reactor coolant pumps, diesels, and the control room;
- (c) systems or portions of systems that are connected to the reactor coolant pressure boundary and are capable of being isolated from that boundary during all modes of normal reactor operation by two valves, each of which is either normally closed or capable of automatic closure; and
- (d) systems, other than radioactive waste management systems, not covered by items (a) through (c) above that contain or may contain radioactive material and whose postulated failure would result in conservatively calculated potential offsite doses that exceed 0.5 rem to the whole body or its equivalent to any part of the body.

The Quality Group D standards given in Table 1 of RG 1.26 should be applied to water- and steam-containing components that are not part of the reactor coolant pressure boundary or included in Quality Groups B or C, but are part of systems or portions of systems that contain or may contain radioactive material.

Safety classification

The simplest safety classification is to divide SSCs into two groups, safety-related (see glossary definition) and nonsafety-related. The safety-related SSCs are then often divided into subclasses that correspond to quality groups A, B and C.

Note: The term “safety-related” being used in this chapter generally corresponds to the term “important to safety,” which is more common internationally.

Safety-related structures, systems and components are required in the US to conform to the quality assurance requirements of 10 CFR 50 Appendix B. Nonsafety-related structures, systems and components have quality assurance requirements applied commensurate with the importance of the item’s function. ASME Standard NQA-1 (ASME, 2009) is used as a basis for implementing a quality assurance program that satisfies the requirements of 10 CFR 50 Appendix B.

Regulators in some countries have developed their own unique safety classification systems (Williams, 2021), which share much in common with US safety classification systems but have their own unique features. For example, the plant function to provide spent fuel pool cooling following a design basis accident is not considered to be safety-related in the US due to it being a longer-term need, but it is treated as safety-related in many European countries.

In recent years, risk-based safety classification systems have been developed that can potentially be used to replace the traditional safety classification system. Regulatory Guide 1.201 (US NRC, 2006), “Guidelines for Categorizing Structures, Systems, and Components in Nuclear Power Plants According to Their Safety Significance,” describes a method that the NRC staff considers acceptable for use in complying with the Commission’s requirements in 10 CFR 50.69 with respect to the categorization of SSCs that are considered in risk-informing special treatment requirements. This categorization method uses the process that the Nuclear Energy Institute (NEI) described in Revision 0 of its guidance document NEI 00-04 (NEI, 2005), “10 CFR 50.69 SSC Categorization Guideline,” dated July 2005. Specifically, this process determines the safety significance of SSCs and categorizes them into one of four risk-informed safety class (RISC) categories.

IAEA Safety Series Guide SSG-30 (IAEA, 2014), “Safety Classification of Structures, Systems and Components in Nuclear Power Plants,” also provides guidance for a risk-based safety classification system.

Defense in depth and diversity

When most operating plants were originally designed, safety systems were generally designed with multiple redundant trains in order to meet reliability goals for the system being able to perform its design function on demand. Failure data for individual system components was used to calculate the probability of successful system operation on demand. In addition, safety systems operating on different principles (e.g., steam-driven versus motor-driven pumps) were included in many plant designs. Design basis accident analyses at this time only required the plant designer to postulate a single active component failure when evaluating the acceptability of emergency core cooling system (ECCS) performance during loss-of-coolant (LOCA) events.

More recently, probabilistic risk assessment (PRA), also known as probabilistic safety assessment (PSA), techniques were developed to provide a more in-depth evaluation of overall plant safety. These assessments allowed the plant designer to determine the relative safety significance of individual plant components, functions and initiating event types. PRA techniques also made it possible to determine plant vulnerabilities to common cause failures of like equipment that might exist in multiple plant systems. If the PRA analysis shows specific initiating events as large contributors to overall plant risk of core damage, the plant designer can then revise the plant design to lessen the significance of the identified vulnerabilities.

With the development of digital instrumentation and control (I&C) systems, the vulnerability to common cause failure (CCF) has increased because digital I&C systems are potentially vulnerable to CCF caused by software errors or software developed logic, which could defeat the redundancy achieved by hardware architecture (Upadhyaya and Wood, 2021). Based on reviews of the Advanced Light Water Reactor Design Certification applications for designs that use digital safety systems, the US NRC has established the following four-point position on defense in depth and diversity in Branch Technical Position (BTP) 7-19 of NUREG-0800 (US NRC, 2016a) for new reactor designs and for digital system modifications to operating plants.

Point 1 “The applicant shall assess the defense-in-depth and diversity of the proposed instrumentation and control system to demonstrate that vulnerabilities to common-mode failures have adequately been addressed.”

Point 2 “In performing the assessment, the vendor or applicant shall analyze each postulated common-mode failure for each event that is evaluated in the accident analysis section of the safety analysis report (SAR) *using best-estimate methods*. The vendor or applicant shall demonstrate adequate diversity within the design for each of these events.”

Point 3 “If a postulated common-mode failure could disable a safety function, then a diverse means with a documented basis that the diverse means is unlikely to be subject to the same common-mode failure, shall be required to perform either the same function or a different function. *The diverse or different function may be performed by a nonsafety system if the system is of sufficient quality to perform the necessary function under the associated event conditions.*”

Point 4 “A set of displays and controls located in the main control room shall be provided for manual, system-level actuation of critical safety functions and monitoring of parameters that support the safety functions. The displays and controls shall be independent and diverse from the safety computer system identified in Items 1 and 3 above.”

The term “best-estimate methods” in Point 2 is more accurately referred to as “realistic assumptions,” which are defined as normal plant conditions corresponding to the event.

The above four-point position is based on the US NRC concern that software-based or software logic based digital system development errors are a credible source of CCF. In this guidance, common software includes software, firmware and logic developed from software-based development systems. Generally, digital systems cannot be proven to be error-free and, therefore, are considered susceptible to CCF because identical copies of the software-based logic and architecture are present in redundant divisions of safety-related systems. Also, some errors labeled as “software errors” (for example) can result from errors in the higher-level requirements specifications used to direct the system development that fail in some way to represent the actual process. Such errors place further emphasis on the need for diversity to avoid or mitigate CCF.

The industry response to these BTP 7-19 requirements has been to allow plant safety systems to be initiated by two independent and diverse I&C systems to the extent practicable. When this isn’t possible, the diverse I&C system activates alternative diverse systems that were not credited in the standard accident analysis.

IAEA safety guides

Two key top-level International Atomic Energy Agency (IAEA) safety documents related to design and operation of nuclear power plants are listed below. They are supported by a number of individual safety guides on various topics.

SF-1 fundamental safety principles

Safety Fundamentals Guide SF-1 (IAEA, 2006) establishes the fundamental safety objective, safety principles and concepts that provide the bases for the IAEA’s safety standards and its safety related program. Related requirements are established in the Safety Requirements publications. Guidance on meeting these requirements is provided in the related Safety Guides. The fundamental safety objective is to protect people and the environment from harmful effects of ionizing radiation. The 10 principles discussed in this guide are as follows:

- Principle 1: Responsibility for safety
- Principle 2: Role of government
- Principle 3: Leadership and management for safety
- Principle 4: Justification of facilities and activities
- Principle 5: Optimization of protection
- Principle 6: Limitation of risks to individuals
- Principle 7: Protection of present and future generations
- Principle 8: Prevention of accidents
- Principle 9: Emergency preparedness and response
- Principle 10: Protective actions to reduce existing or unregulated radiation risks

SSR-2/1 (Rev. 1) safety of nuclear power plants: Design

Specific safety requirements publication SSR-2/1 (IAEA, 2016) establishes design requirements for the structures, systems and components of a nuclear power plant, as well as for procedures and organizational processes important to safety that are required to be met for safe operation and for preventing events that could compromise safety, or for mitigating the consequences of such events, were they to occur.

It is intended for use by organizations involved in design, manufacture, construction, modification, maintenance, operation and decommissioning for nuclear power plants, in analysis, verification and review, and in the provision of technical support, as well as by regulatory bodies.

Operational design requirements

In addition to the many safety design requirements, there are also operational design requirements that must be considered. Plant control systems and the systems they control need to be designed to minimize the probability of inadvertent plant trips that could

adversely affect plant availability and might also challenge plant safety systems. Plant designers typically design these systems so that inadvertent trips of pumps can be accommodated without a reactor scram. Plants that have installed at least 100% turbine bypass capacity have the capability to avoid a reactor scram for inadvertent turbine trips or generator load rejection events. A typical goal is to design the operational systems with sufficient redundancy so that the reactor scram frequency is less than once per year over the life of the plant, and with an overall plant availability of greater than 90%.

NRC recommendations for plant organizational and staffing requirements are provided in Chapter 13 of the Standard Review Plan, NUREG-0800. This SRP chapter also provides requirements for training of operating personnel, emergency planning, physical security, cyber security and fitness for duty.

Technical specifications for plant operation

Each nuclear power plant is required to establish Technical Specifications that are used to ensure the plant is operated in accordance with its established design basis.

Technical Specifications are required by 10 CFR 50.36 and include specific requirements in the following categories:

Safety limits are limits upon important process variables that are found to be necessary to reasonably protect the integrity of certain physical barriers that guard against the uncontrolled release of radioactivity (Lutz and Williamson, 2021). If any safety limit is exceeded, the reactor must be shut down. The licensee shall notify the Commission, review the matter, and record the results of the review, including the cause of the condition and the basis for corrective action taken to preclude recurrence. Operation must not be resumed until authorized by the Commission.

Limiting safety system settings are settings for automatic protective devices related to those variables having significant safety functions.

Where a limiting safety system setting is specified for a variable on which a safety limit has been placed, the setting must be so chosen that automatic protective action will correct the abnormal situation before a safety limit is exceeded. If, during operation, it is determined that the automatic safety system does not function as required, the licensee shall take appropriate action, which may include shutting down the reactor. The licensee shall notify the Commission, review the matter, and record the results of the review, including the cause of the condition and the basis for corrective action taken to preclude recurrence.

Limiting conditions for operation are the lowest functional capability or performance levels of equipment required for safe operation of the facility. When a limiting condition for operation of a nuclear reactor is not met, the licensee shall shut down the reactor or follow any remedial action permitted by the technical specifications until the condition can be met.

Surveillance requirements are requirements relating to test, calibration, or inspection to assure that the necessary quality of systems and components is maintained, that facility operation will be within safety limits, and that the limiting conditions for operation will be met.

Design features to be included are those features of the facility such as materials of construction and geometric arrangements, which, if altered or modified, would have a significant effect on safety and are not covered in categories described above.

Administrative controls are the provisions relating to organization and management, procedures, recordkeeping, review and audit, and reporting necessary to assure operation of the facility in a safe manner.

Design for maintenance

Most advanced reactors are designed with sufficient redundancy to accommodate continued operation with one division of safety equipment out of service and still be able to meet all analytical design requirements with one additional single failure. This capability allows significant maintenance to be performed on-line in areas of the plant that are accessible during normal operation. By performing significant maintenance during normal operation, refueling outage lengths can be shortened, leading to increased plant availability.

To facilitate ease of maintenance, building and component layouts should be arranged to provide adequate access for maintenance personnel and easy access to lifting devices where needed. For equipment that is expected to require replacement during plant operation, a pathway that allows for removal and replacement should be provided.

Glossary

AP1000 Advanced Plant 1000 MWe – a Westinghouse passive type Generation 3 PWR plant.

APR1400 Advanced Pressurized Reactor 1400 MWe - a South Korean (KHNP) PWR system.

ABWR The General Electric designed Advanced BWR reactor system.

BWR Boiling Water Reactor – A single coolant loop reactor type in which steam is generated directly inside the reactor vessel.

B&W Babcock & Wilcox.

CE Combustion Engineering.

CPR1000 A Chinese Generation 2 PWR plant.

CVCS Chemical Volume Control system – a system that controls the water inventory, boric acid concentration, and chemistry of the primary Reactor Coolant System.

DNB Departure from Nucleate Boiling – a PWR fuel clad design limit which represents the onset of film boiling resulting in a significant loss of heat transfer and increase in fuel clad temperature.

EPR Evolutionary Pressurized Reactor – a Framatome PWR system.

ECCS Emergency Core Cooling System.

EFWS Emergency Feed Water system – An auxiliary system used to supply secondary feedwater to the steam generators when the normal feedwater supply is not available.

ESBWR The General Electric Economic Simplified BWR reactor system.

HPSI Pump High Pressure Safety Injection – Pump used to supply cooling water immediately following a LOCA or rapid RCS cooldown event when the RCS is pressurized.

Letdown The process by which primary reactor coolant is extracted from the RCS in small amounts during operation and full pressure conditions.

LOCA Loss of Coolant Accident – An accident involving loss of primary cooling water to the reactor core.

LPSI Pump Low Pressure Safety Injection – Pump used to supply cooling water during shutdown or following a LOCA when the RCS is depressurized.

Once-through SG A type of steam generator for PWRs in which the primary coolant enters at the top of the generator and is passed downward straight tubes to transfer heat to the secondary coolant.

Pellet Power peaking factor The ratio of maximum fuel pellet power to the average fuel pellet power.

Pressurizer The component of the RCS that maintains primary system pressure during normal operation.

PWR Pressurized Water Reactor.

Radial Power peaking factor The ratio of maximum fuel rod power to the average fuel rod power.

RCP Reactor Coolant Pump – Use in PWRs to maintain flow of the primary coolant through the reactor vessel.

RCS Reactor Coolant System – The primary coolant circuit of a PWR that provides pressurized coolant to the reactor core.

Reactivity The extent of the deviation in the core effective multiplication factor (usually denoted as k_{eff}) from its value at a just critical state (at which state $k_{\text{eff}} = 1.0$ and the fission rate is constant). A positive (negative) reactivity implies that the ratio of

the rate of neutron production to the rate of neutron losses (k_{eff}) is larger (smaller) than 1.0 due to a change in a performance characteristic such as temperature or density.

Reactor trip A shutdown signal actuating the reactivity control system of the reactor to quickly release all control rods into the core, shutting down the reactor.

RHR Residual Heat Removal – An auxiliary secondary cooling system that does not utilize the steam generators to cool the primary coolant during shutdown or post-LOCA condition.

RT_{NDT} Nil ductility transition temperature; the temperature below which steel transitions from a ductile to a brittle fracture mechanism.

RWT Refueling Water Tank – a storage tank filled with borated water that is used to auxiliary cooling of the reactor during shutdown or follow a LOCA.

Scram A sudden shutdown of the self-sustaining fission reaction by the sudden drop of several control rods into the reactor core (i.e. Safety Control Rods Activation Mechanism). Also known as a reactor trip.

SIT Safety Injection Tank (also called Accumulators in some designs) – A tank containing pressurized borated water used for reflooding the reactor core immediately after a large break LOCA.

USNRC United States Nuclear Regulatory Commission.

U-tube SG A type of steam generator for PWRs in which the primary coolant is passed through U-bend tubes to transfer heat to the secondary coolant.

VVER A Russian type Generation 2+ PWR using hexagonal fuel assemblies.

Introduction

The Pressurized Water Reactor Design was first developed as the power propulsion plant for US submarines (Anand and Herring, 2021), but was later applied to civilian electric power production. See Maldonado and Brown (2021) for a more detailed history of the PWR. Today 297 of the 448 power reactors in the world are based on the Pressurized Water Reactor (PWR) design. Moreover, 78 of the currently planned¹ 94 power reactors will be PWRs. The reason for this has been the large accumulated operating experience, proven reliability, and relative simplicity of operation. PWR plants are currently operating with electrical power ratings up to 1400 MWe at a reactor power of 4000 MWth (Hamon, 2021a).

PWR overview

The Pressurized Water Reactor (PWR) nuclear steam supply system (Fig. 1) is characterized by a two coolant stage design (i.e., a primary and secondary coolant circuit) in which the primary water coolant is maintained above saturation pressure such that no significant amount of boiling occurs in the reactor core during normal operation. The steam for the turbine-generator is produced in a separate steam generator where the heat from the primary coolant is transferred to a secondary water coolant stage at lower pressure. The coolants of primary and secondary coolant stages are separated and never in direct contact. The steam produced in the steam generator is at or near saturation conditions. This concept has the major advantage of maintaining fully moderated conditions in the reactor core at all times while providing an additional barrier to the potential release of radionuclides during severe accident situations.

Fig. 1 shows the basic PWR system configuration. The reactor vessel containing the fuel may be connected to two, three, or four steam generators, each having a supporting reactor coolant pump on the return cold leg. The pressurizer is required to maintain and control primary pressure at an operating pressure of approximately 2200 psi (15.2 MPa). Table 1 shows typical PWR system operating parameters.

Reactor core and fuel assemblies

In a PWR the reactor core water coolant/moderator is maintained at nearly equal density inside the reactor vessel thus enabling nearly optimal moderated conditions everywhere in the core during normal operation. Maintaining a fully moderated core results in a core power distribution that is relatively uniform² with lower power peaking factors. Since the core power is limited by margin of the hottest rod to fuel design limits, such as Departure from Nucleate Boiling (DNB) and fuel centerline melt temperature, lower power peaking factors mean that the core can be operated at a higher power density than a BWR without exceeding the fuel design

¹As of end of 2019.

²Relative to a Boiling Water Reactor (Hamon, 2021a, b) core in which the water density becomes lower with elevation making the upper part of the core undermoderated.

limits, thus allowing a smaller core size for a given total power. The fuel is also limited by peak rod burnup,³ which is meant to protect against fuel rod failure due to fuel clad corrosion during normal operation and anticipated operational occurrences (Young, 2021a). Operation with lower power peaking factors means that the fuel can be discharged at a higher average burnup, thus greatly improving the fuel utilization and fuel cycle cost relative.

The PWR core (Fig. 2) is comprised of fuel assemblies configured in a semi-cylindrical shape that approximates an optimal geometry for nuclear criticality.⁴ The fuel assembly consists of the nuclear fuel pellets contained within fuel rods that are bundled into fuel assemblies. The UO₂ fuel pellets, typically enriched to 4–5 wt% U235, are typically 0.74–1.0 cm in diameter and approximately 1.3–2.5 cm long. A 3.66 m stack of these pellets are loaded into a sealed zirconium alloy fuel rod tube that is typically 20–30 cm longer than the stack of fuel pellets in order to provide space for the accumulation of gaseous fission products released during operation. Some of the fuel rods may contain a burnable absorber (Young, 2021b) such as boron, gadolinia,⁵ or erbia in the form of an admix to the UO₂ or in a coating applied to the pellet that provides extra neutron absorption for a portion of the cycle to assist in offsetting the core excess reactivity during the early portions of the reactor operating cycle.

The fuel assemblies (Fig. 3) combine up to 264 fuel rods in a 4 m tall steel-Inconel-zircaloy “skeleton” to provide structural integrity of the active core and also to serve as the container for loading and unloading fuel from the reactor core. The fuel assembly skeleton consists of the bottom nozzle, fuel assembly grids, top nozzle as well as various thimble tubes to provide structural support and to guide the control rods and in-core instrumentation into the core.

The steel bottom nozzle contains support legs that fit into the alignment features in the bottom core support plate. It also contains a flow plate to evenly channel the coolant flow distribution to the coolant channels between the fuel rods. The bottom nozzle may also contain a debris filter to catch and hold metallic debris (usually material that was inadvertently introduced during the refueling outage) that could damage the fuel clad during operation.

Fig. 2 PWR reactor core cross section. Westinghouse Electric Company (1984) *The Westinghouse Pressurized Water Reactor Nuclear Power Plant*.—Courtesy Westinghouse Electric Company.

³Burnup is a measure of the amount of energy generated via fissions per unit weight of uranium loaded into the core.

⁴For establishing and sustaining a fission chain reaction.

⁵Gadolinium oxide (Gadolinia) or Erbium oxide (Erbia).

Fig. 3 PWR Fuel Assembly (Westinghouse). Westinghouse Electric Company (1984) *The Westinghouse Pressurized Water Reactor Nuclear Power Plant*.—Courtesy Westinghouse Electric Company.

The fuel assembly grids are the structures that hold the fuel rods into the tightly spaced array required for optimal nuclear performance and adequate cooling of the fuel rods. Each grid consists of strips that contain spring-like structures that allow insertion (and sometimes removal) of the fuel rod, but still have sufficient contact force to secure the fuel rod. The grids are attached to the guide thimbles at various elevations within the skeleton. The grids in the active core region are usually made of zirconium alloy in order to minimize parasitic neutron absorption. Some of these grids may have mixing vanes to thermally mix the coolant flowing upwards in the channels between fuel rods to improve heat transfer, reduce hot spots on the fuel rod clad, and increase DNB margin. In addition, some fuel assembly designs incorporate “intermediate flow mixing” grids that contain mixing vanes, but do not provide structural rod support.

The steel top nozzle contains features to interface with the top fuel alignment plate and maintain the fuel assembly spacing. The top nozzle also contains hold down springs that allow for fuel assembly thermal expansion during operation, while maintaining sufficient hold down force to prevent “liftoff” of the fuel assembly from the high velocity reactor coolant flow.

Approximately one third to one half of the fuel assemblies are replaced at each refueling shutdown which may occur at 12, 18, or 24 month intervals. The fresh assemblies are judiciously placed at locations in the core to assure good power sharing and maintain sufficient margin to peak rod power and temperature limits. The carryover fuel is also reshuffled as necessary during the refueling outage in order to meet fuel design limits and to maximize the energy extraction from the fuel prior to final discharge. **Fig. 4A** shows a typical core loading pattern. Some of the fresh assemblies may contain burnable absorber either within the fuel pellet or in discrete burnable absorber rods inserted into the assembly thimble guide tubes. The burnable absorber rods are judiciously placed within the fuel assembly (See **Fig. 4B**) to minimize the power peaking and to assure maximum fuel burnup by the end of cycle.

The reactor core also contains other components such as control rods and in-core instrumentation and, in some cases, discrete burnable absorber rods, neutron startup sources, and special isotope (e.g. Co-60, H3) generation capsules that are inserted in the guide thimbles for a single cycle of operation.

Control rods containing B4C, Ag-In-Cd, or hafnium are inserted into some or all of the guide thimbles in approximately half of the fuel assemblies to control reactor power. The control rod absorber in most PWRs is contained in tubes which are inserted into up to 24 of the guide thimbles in the assembly. The control rod fingers for Combustion Engineering PWRs are larger and are inserted

Fig. 4 Typical PWR Core and Assembly Fuel Loading Pattern. (A) Core Loading Pattern. (B) Assembly Rod Loading. Westinghouse Electric Company (1984) *The Westinghouse Pressurized Water Reactor Nuclear Power Plant*.—Courtesy Westinghouse Electric Company.

into four or five large guide tubes that occupy a 2×2 rod cells in the assembly. A few PWR plants (e.g. Palisades Nuclear Generating Station in Michigan) still use the cruciform control blades similar to BWRs that are inserted into the gaps between fuel assemblies.

The control rods are assigned to rod groups (Fig. 5A) that are electrically controlled together based on their function during normal reactor operation. Some groups are designated as regulating groups that are inserted in a pre-defined sequence to control reactor power or to change core power or to offset core excess reactivity. Some groups are designated as shutdown groups that are only inserted during a reactor scram or during shutdown. In some cases, a control rod group may be designated as a power shaping rod group to control the reactor axial power distribution. Power shaping control rods may be composed of weaker neutron absorbers such as tungsten or Inconel. The control rods in a PWR are normally held above the active core by magnetic grips which release and allow the rods to drop into the core following a reactor scram or loss of electrical power. This is one of the primary engineered safety features of this reactor type (Lutz and Williamson, 2021).

In order to assure that the fuel rod integrity is maintained during normal operation and during anticipated operational occurrences, such as loss of load or loss of offsite power, two key power distribution parameters are monitored to assure they stay within

Fig. 5 Locations of Control Rods and Incore Instruments. (A) Control Rod Locations. (B) Incore Instrument Locations. Westinghouse Electric Company (1984) *The Westinghouse Pressurized Water Reactor Nuclear Power Plant*.—Courtesy Westinghouse Electric Company.

predefined limits. These parameters are the peak rod power, which is related to the margin to DNB of the fuel rod clad and the peak pellet power, which is related to the margin to fuel centerline melt and to the peak clad temperature during a Large Break Loss of coolant accident (Rempe, 2021).

The monitoring of these limits is performed using in-core neutron flux detectors and thermocouples which are located in the center thimble tube of approximately a fourth of the fuel assemblies (Fig. 5B). The in-core flux detectors may either be fixed and always inserted during operation, or movable that are normally withdrawn but periodically (usually monthly) inserted to obtain a core flux map. Fixed in-core detectors depend on the beta decay of activated rhodium or vanadium or by gamma interaction to obtain a signal proportional to the local fission power level. Movable in-core instruments are usually small fission chambers that are sequentially driven into each of the “instrumented” assemblies on a monthly basis.

The data obtained from the in-core instruments are used to determine a detailed power distribution map for all locations in the core in order to confirm compliance with power peaking limits. Since most in-core detectors have a delayed response, or in the case of movable detectors are not continuously used, they are currently only used for monitoring core limits during normal operation and are not used by the reactor protection system to initiate a reactor trip. Reactor protection systems currently use the prompt responding ex-core neutron detectors, which are located immediately outside the reactor vessel, to determine instantaneous reactor power and core axial power distribution to initiate a reactor trip if maximum core power, power peaking, or power rate increase limits are exceeded.

Reactor vessel and internals

The PWR reactor vessel (Fig. 6) is the pressure vessel used to contain and support the reactor core. The reactor vessel is designed and manufactured to the requirements of Section III of the ASME Boiler and Pressure Vessel Code. The vessel is fabricated from low carbon steel with a diameter up to 6.7 m (22 ft) and thickness of approximately 25 cm (10 in.). The inside surface in contact with coolant is clad with a minimum of 0.32 cm austenitic stainless steel to minimize corrosion from the boric acid⁶ containing coolant. The removable upper head of the reactor vessel contains a bolting flange employing studs and nuts. Hydraulic tensioning of the studs permits uniform nut loading. Two hollow, metallic O-rings form a pressure-tight seal in concentric grooves in the head flange. The reactor vessel is supported by steel pads integral with the coolant nozzles. The pads rest on steel base plates atop a support structure attached to the concrete foundation. An elongation gauge is employed to facilitate uniform loading.

Primary coolant inlet and outlet nozzles are located near the top of the vessel at an elevation above the top of the active core such that the core will remain covered with coolant in the event of a break in one of the coolant pipe legs. The removable top head

⁶Soluble boron in the form of boric acid is added to the coolant via the CVCS (See discussion later in this chapter) in order to provide core reactivity control.

Fig. 6 PWR Reactor Vessel. Westinghouse Electric Company (1984) *The Westinghouse Pressurized Water Reactor Nuclear Power Plant*.—Courtesy Westinghouse Electric Company.

contains penetrations for the control rods and in-core instruments. (In some PWR designs the in-core instrument enters through the bottom of the reactor vessels in order to have a straight path for insertion into the bottom of the fuel assembly.)

Reactor pressure vessel design and operation requires allowance for changes in steel properties due to fast neutron irradiation of the vessel wall surrounding the core. These changes in properties include increased ultimate and yield strengths, and decreased notch ductility, the latter being characterized as an increase in the nil ductility (embrittlement) transition temperature (RT_{NDT}) of the steel. The shift in RT_{NDT} from an initial temperature to a higher temperature is a function of the fast neutron fluence (nvt) and amount of shift sets limits on the maximum allowable pressure during heatup and cooldown for the vessel and may ultimately limit the operating life of the plant. (The allowable increase in RT_{NDT} is limited by a concern that over pressurization of the reactor vessel or the reflood of the reactor vessel following a Loss of Coolant Accident with the relatively cold water from the Emergency Core Cooling System could lead to vessel fracture if the RT_{NDT} temperature were high enough.)

The fast neutron fluence is predicted by neutron transport calculations that are benchmarked to “surveillance” capsules located between the neutron shield pads and the vessel wall directly opposite the center of the core. The surveillance capsules contain reactor vessel steel specimens obtained during vessel fabrication as well as other dosimeter materials, which are material samples that are used to obtain the nvt at these locations. Surveillance capsules are periodically extracted from the vessel and tested to determine the nvt (from the dosimeter materials) and the RT_{NDT} (from the vessel specimens) to assure that the predicted RT_{NDT} shift for the reactor vessel at End of plant Life will be within acceptable limits.

Reactor vessels in the early PWR plants were fabricated by welding three sections of curved plates into rings which were then welded into the vessel cylinders since there were no forges large enough to forge a cylinder of that diameter. However, this approach placed vertical welds at the location of the reactor core which raised a concern of weld failure due to prolonged exposure to high energy neutrons especially for plant lifetime extension beyond 40 years. Today, there are facilities capable of forging the large rings required to fabricate large PWR reactor vessels without beltline welds at the active core elevation that can achieve operating lifetimes of 80 years or longer.

The reactor internals are removable structures inside the reactor vessel that are required to support the core and to establish the flow path for coolant flow from reactor vessel inlet nozzle, through the fuel region, and out the reactor vessel outlet nozzle. The reactor internals are divided into two major structures: the upper internals and the lower internals. The upper internals include the top support plate, the upper core plate, support columns, and control rod guide structures the function of which is to align and locate the upper ends of the fuel assemblies, to protect withdrawn control rod clusters from lateral forces due to coolant cross-flow, and to guide the control rod cluster and associated drive shaft. The principal components of the lower internals are the lower core support plate and the core barrel whose functions are to support the weight of the core, to align and position the lower ends of the fuel assemblies and to reduce the radiation dose to the reactor vessel wall. Some plants have lower plenum instrument tubes to guide the in-core instrumentation into their proper core locations.

In addition to the upper and lower internals, there is the core baffle (or shroud) that encloses the active core, for which the main purpose is to channel the coolant flow into the active core region. This component experiences the highest exposure to neutron flux and gamma heating of any of the non-fuel components and thus it requires special attention when plant lifetime extension is being considered.

The reactor vessel is located in the reactor refueling cavity in the containment building floor which is flooded with water during refueling to provide radiation shielding to personnel in containment during movement of the spent fuel assemblies. During operation the reactor cavity is covered with a missile shield in order to protect the control rod drives during a severe accident.

Steam generator

Modern PWR plants have two to four steam generators to generate steam to drive the turbine and to cool the primary coolant and thus reactor core. In a PWR steam generator, the pressurized primary coolant is channeled through a large number of tubes that are immersed in a reservoir of low pressure secondary coolant to which the primary heat is transferred in sufficient amount to generate steam. The steam generators for most modern PWRs power plants come in three basic configurations: vertical U-tube in which the primary coolant tubes enter and exit at the bottom of the steam generator, vertical once-through in which the primary coolant enters on top and exits at the bottom, and horizontal steam drum generator in which the steam is generated in a generator tank and then collected into a secondary header tank similar to the configuration used in large fossil plants. All steam generator configurations, except for the vertical once-through, produce saturated steam. The vertical once through steam generator (used in B&W PWRs) is capable of producing slightly superheated steam which results in a small increase in plant thermodynamic efficiency. Most modern PWRs employ the U-tube design that allows for a relatively small compact steam generator and thus smaller containment building.

The U-tube steam generator (Fig. 7) consists of three sections: a lower plenum region, an evaporator section and a steam drum section. The lower plenum region is divided into two halves, one connected to the primary coolant hot leg and one connected to the primary coolant cold leg. Hot primary coolant enters the hot side and is diverted into U-tubes that sit in the evaporator section. Cool primary coolant return from the U-tube on the cold plenum side and is channeled into the primary cold leg. Cold secondary feed-water coolant is injected into an annulus region surrounding the tube bundle near the top of the generator and is preheated while it flows to the bottom of the evaporator section. The evaporator section is filled with secondary coolant that covers the U-tubes. Heat transfer from the primary coolant in the U-tubes generates steam in the secondary coolant. This steam then enters the steam drum section in the upper part of the steam generator that contains moisture-separating equipment, which delivers the high quality saturated steam required to minimize turbine blade damage.

The B&W PWR plants use two once-through steam generators capable of producing steam with a few degrees superheat. In the B&W design (Fig. 8), hot primary coolant enters the top of the steam generator and exits the bottom, thus allowing heat transfer from the hottest primary coolant to the saturated steam generated in the lower elevations of the steam generator thus resulting in a few degrees of superheat.

The tubes in most of the original PWR steam generators are fabricated from mill-stressed Inconel 600, which proved to be susceptible to stress corrosion cracking in the upper portions of the steam generator where rapidly fluctuating water levels induce vibration and rapid changes in temperature. As tubes failed, they were plugged to prevent leakage of primary coolant to the secondary system. Many plants have replaced their original steam generators with generators which have tubes made of heat treated Inconel 690, which has proved to be significantly less susceptible to cracking.

Fig. 7 PWR U-Tube Steam Generator (CE Type). System 80+ Design Control Document (1997) Available in the NRC Public Documents Archive.

Reactor coolant pump

A Reactor Coolant Pump (RCP) is attached to each primary cold leg to maintain the high primary flow rate needed to provide sufficient cooling of the PWR reactor core. In the typical PWR RCP (**Fig. 9**), reactor coolant is pumped by an impeller attached to the bottom of the rotor shaft. Each RCP on a typical 4-loop Westinghouse plant has an operating speed of 1189 rpm and delivers about 97,600 gpm (6158 l s^{-1}) of coolant to the reactor vessel. The coolant is drawn up through the bottom of the casing, up through the impeller, and discharged through the diffuser and an exit nozzle in the side of the casing. A diffuser and turning vane assembly converts velocity head from the impeller to pressure head, and directs the flow to the single discharge nozzle in the circular casing. A thermal barrier incorporated as an integral part of the diffuser and turning vane assembly limits the heat transfer from the casing into the seal and bearing regions. The impeller is driven by an AC induction motor mounted on top of the pump assembly.

A unique design problem for the PWR RCP is the design of the seals where the motor shaft passes through the pump casing. The seal must seal against a pressure head of $> 15.2 \text{ MPa}$ (2200 psi) while still allowing the pump shaft to rotate at a high speed. The

Fig. 8 B&W Straight thru Steam Generator. Babcock and Wilcox (1992) *Steam – Its Generation and Use*, 40th edn.

solution has been to allow a small amount of primary coolant leakage, about $\sim 0.23\text{--}0.68\text{ m}^3\text{ s}^{-1}$ ($\sim 1\text{--}3\text{ gal/min}$), through the seal to form a barrier but still allow for pump rotation. The Generation 3 Westinghouse AP1000^{®7} nuclear power plant employs canned

RCP pumps similar to, but much larger than, those used in nuclear submarines. In the canned reactor coolant pump design there is no pump shaft as the rotor, and stators are completely sealed inside the pressure boundary while the induction motor coils are wrapped outside the pump housing (See Fig. 10). This design completely eliminates the problem of pump seal leakage.

Another consideration in PWR RCP design is that the impeller must have sufficient inertia such that in the event of loss of AC power, the decrease in Reactor Coolant System (RCS) flow will be slow enough to allow for sufficient reactor power decrease

Fig. 10 AP1000® plant “Canned” Reactor Coolant Pump. Westinghouse Electric Company (2007) *Westinghouse AP1000 Design Control Document - Tier 2, Rev. 16*, (available in NRC Adams system Number: ML071580759 to ML071580937).

following a reactor trip to avoid DNB fuel failure. For the canned RCP pump design this often requires the addition of an extra flywheel since the pump impellers lack the inertia of the motor shaft.

At full capacity the Reactor Coolant Pumps delivers a net thermal power to the primary coolant of about 12 MWth. The RCP heat, in combination with the pressurizer heaters, is used to heat up the RCS to operating temperature ($\sim 288^\circ\text{C}/550^\circ\text{F}$) prior to bringing the core to critical.⁸

Pressurizer

The function of the pressurizer (**Fig. 11**) is to maintain the RCS pressure during steady-state operation and to limit pressure changes during system transients. This function is accomplished by maintaining and managing a steam bubble in the top $\sim 40\%$ of the

⁸A critical core is a core that sustains a fission chain reaction.

Fig. 11 Pressurizer. Westinghouse Electric Company (1984) *The Westinghouse Pressurized Water Reactor Nuclear Power Plant*.—Courtesy Westinghouse Electric Company.

pressurizer. Electric immersion heaters, located in the bottom of the pressurizer vessel, keep the water at saturation temperature and maintain a constant system operating pressure of approximately 15.2 MPa (2200 psi). Activation of the heaters results in an increase in system pressure. System pressure is decreased by injecting reactor coolant from the cold leg of a coolant loop through the spray nozzle located at the top of the pressurizer to condense the steam bubble. The pressurizer steam bubble also compensates for potential system pressure changes resulting from changes in the primary coolant temperature due to changes in turbine load. A reduction in primary coolant outlet temperature will increase the water density, and thus the level, decreasing the pressure above the water level, which results in some of the water in the pressurizer flashing to steam, thus increasing and restoring the primary system pressure. Likewise, an increase in primary coolant temperature will increase the pressure inside the pressurizer resulting in condensation of the pressurizer steam bubble thus decreasing and restoring the primary system pressure. This results in a natural tendency for the PWR RCS to follow moderate changes in the turbine demand. Flexible operations, which are intentional changes in reactor power are discussed in [Young \(2021b\)](#). The pressurizer heaters, in combination with heat imparted to the coolant by the Reactor Coolant Pumps, are also used to heat up the RCS to operating temperature ($\sim 550^\circ\text{F}$) prior to bringing the core to critical.

Emergency core cooling system

All nuclear power plants are required to have an emergency core cooling system (ECCS) that can rapidly inject coolant into the reactor core during accident situations (Rempe, 2021). The emergency systems are required to have redundant components to assure that the safety function is maintained even in the event of a failure of a key component. The ECCS for a PWR requires unique design considerations due to the large pressure of the primary coolant. For this reason, a PWR ECCS consists of two coolant delivery systems, one for high pressure injection and one for low pressure injection (See Fig. 12). The ECCS system is designed to provide not only emergency core cooling, but also continued cooling during the long-term phase following the accident.

The initial source of the ECCS water is the highly borated water contained in the Safety Injection (or Accumulator) Tanks, which are located inside the containment building. The accumulators deliver water by passive gravity feed to the cold leg and are designed to rapidly and completely reflood the core following a large break Loss of Coolant Accident (LOCA). The High Pressure and Low Pressure Safety Injection (LPSI) pumps, which are located outside but close to containment, draw cooling water from the Refueling Water Tank (RWT). When the RWT water is nearly depleted, the system automatically switches the source of the Injection pump to the containment sump. The LPSI pumps continue to inject water from the containment sump to the cold leg until the system is manually realigned to inject to the hot leg. The purpose of this re-alignment is to terminate boiling in the core and to prevent the buildup of precipitated boron from interfering with core cooling following a large cold-leg break.

The Emergency Feedwater System (EFWS) is used to supply feedwater to the steam generators following accident or transient conditions when the main feedwater system is not available. The EFWS thereby maintains the capability of the steam generators to remove plant stored heat and core decay heat by converting the emergency feedwater to steam which is then discharged to the condenser or to the atmosphere. The EFWS is also capable of supplying feedwater to the steam generator during normal plant operations of startup, shutdown, and hot standby.

The power for the Emergency Core cooling systems is normally supplied from the offsite electrical grid (which also must have redundant connections). In the event of loss of offsite power, there are two onsite emergency diesel generators which are automatically started. As a final backup, there are two sets of battery packs that are designed to maintain the emergency core cooling function from 2 to 4 h after loss of all other power.

Reactor containment

The nuclear steam system for all PWR power plants are enclosed in a large steel lined ~40 in. thick concrete containment building (Fig. 13). The primary function of the containment building is to contain and control any release of radioactivity to the environment under normal, upset, or emergency conditions including severe earthquakes (Sharpe, 2021). A PWR containment building is much larger than that for a BWR, as there must be sufficient volume to accommodate full and sudden release and subsequent flash of the high pressure RCS coolant to steam without exceeding the containment building stress limits.

The containment contains various systems that are designed to maintain containment integrity even during accident conditions:

- Containment spray system to reduce the containment temperature and pressure
- Containment Cooling System to cool the containment atmosphere during normal and accident conditions
- The Containment Isolation System provides the means of isolating the various fluid systems passing through the containment walls in order to prevent the release of radioactivity to the outside environment in the case of an accident

The Westinghouse AP1000[®] plant uses passive containment cooling (See Fig. 13B) which can function for several days even in the event of a full station blackout event similar to the Fukushima event.

Ancillary PWR components

PWR power plants also contain components required to maintain operation of the plant, and to mitigate consequences during accident situations.

The Chemical Volume Control System (CVCS) which is mainly located in the auxiliary building outside the containment building is used to control water inventory, boric acid concentration, and chemistry of the primary RCS. These functions are satisfied by maintaining a continuous feed-and-bleed stream to and from the RCS during plant operation. Water from the Boric Acid Tank, which contains a highly concentrated solution of boric acid, or the Reactor Water Makeup tank, which contains demineralized pure water, is injected into the RCS by charging pumps, depending on whether the RCS boron concentration is to be increased or decreased. The feed rate to the RCS is automatically controlled by pressurizer water level while the bleed rate can be set by selecting the proper combination of letdown orifices to meet plant operational requirements. Letdown water leaves the RCS and flows through the shell side of the regenerative heat exchanger where it gives up its heat to makeup water before being returned to the RCS. By using this heat exchanger to heat up the makeup water, heat loss from RCS during RCS boration and dilution is minimized.

The primary function of the Residual Heat Removal System (RHRS) is to transfer heat energy from the core and primary Reactor Coolant System to heat exchangers, cooled by the plant's ultimate heat sink (either via a cooling tower, or body of water, such as a river) located outside containment during plant cooldown and refueling operations. The system is designed to reduce the RCS temperature to 140 °F (60 °C) within 20 h following reactor shutdown. The RHRS extracts coolant from a depressurized RCS hot leg and routes it through a heat exchanger located outside containment. During normal plant operation, the RHR pumps and heat exchangers are normally isolated from the RCS in order to preserve the RCS pressure boundary and containment isolation requirements. Cold RHR coolant is returned to the cold leg of the RCS. Provisions are made for continued flow of the reactor coolant to the CVCS during shutdown. The RHRS may also be used to transfer refueling water between the refueling cavity and the refueling water storage tank at the beginning and end of refueling operations. The low pressure RHR pumps can also draw from the containment sump and Refueling Water Tank to provide the Low Pressure Safety Injection cooling to the depressurized RCS system following a LOCA.

Balance of plant components

The components of the secondary and other Balance of Plant Systems are functionally the same as those used in fossil steam plants. The major differences in the secondary system of PWR plants are:

- a) Due to the continuous production of decay heat in the reactor core even while shutdown, the secondary system must always maintain coolant to the reactor. This requirement manifests itself in emergency feedwater pumps and extra heat exchangers. No cooling is needed for a fossil plant during shutdown.
- b) The PWR delivers a high flow of low temperature saturated steam to the turbine whereas a fossil plant delivers a smaller flow of superheated steam. This requires a "wet turbine" design, which has a different turbine blade design than those used in a fossil plant's turbine, which accepts superheated steam for higher thermal efficiency energy conversion.

Operation of PWR

Today most PWRs are operated as large (800–1300 MWe) base load units which are maintained at or near full power conditions during their entire operating cycle. Most PWRs operate on an 18 month refueling schedule with a few plants on 12 or 24 month refueling schedules. PWRs are typically operated with all the control rods fully withdrawn and the core excess reactivity is controlled by a combination of burnable absorber located in the fuel assemblies and boric acid dissolved in the RCS. The RCS soluble boron concentration at the beginning of cycle is usually set at 1000–1300 ppm which is diluted (by the CVCS) to ~10 ppm at the end of the cycle.

Future of the PWR

To date, there are four standardized US PWR designs with thermal power ratings up to 4000 MWth that have been approved through the design certification by the USNRC for future US application: Westinghouse AP600, System80+ and AP1000[®] plants,

and the Korean APR1400 plant (NRC, 2019). Two standard BWR designs, ABWR and ESBWR (Hamon, 2021b) have also been approved. PWRs (EPR) are currently under construction will have power ratings up to 1600 MWe, 4500 MWth. In addition, a significant number of other standard PWR designs are being deployed elsewhere (APR1400-Korea, VVER1000 -Russia, CPR1000- China). There are also several Small Modular Reactor designs, most notably the NuScale SMR (NRC, 2020), based on the PWR design with power ratings less than 100 MWe.

Advancements in material science and PWR core design have allowed for plant lifetime extension beyond the original 40 year design life to 60 years even 80 years in some cases. PWR fuel designs are being tested that will increase the fuel discharge burnup to 80 GWD/MTU or beyond with fuel enrichments up to 10 wt% U235. Given these trends it is clear that the PWR reactor design will likely continue to be a major contributor to the world energy supply for many years to come.

Introduction

The Boiling Water Reactor (BWR) is based on two fundamental principles that distinguish it from other nuclear power plant reactors: (1) bulk boiling of water occurs in the reactor core; and (2) steam produced from boiling in the reactor core is sent directly to the turbine that is used to turn a generator to produce electricity.

The General Electric Company (GE) signed a contract with the Commonwealth Edison Company of Chicago, Illinois, in 1955 to deliver the 180 MWe Dresden Nuclear Station (Unit 1). To assure the success of the Dresden-1 reactor, GE embarked on construction of a smaller scale development plant at its Vallecitos Atomic Laboratory near Pleasanton, California, to develop operational data for the Dresden-1 design. Pacific Gas & Electric Company (PG&E) also participated in the developmental reactor project by supplying a turbine-generator. In 1957 the Vallecitos Boiling Water Reactor (VBWR) became the first privately built atomic power reactor to supply electricity to a public utility grid ([Fig. 1](#)). Additional information about early BWR development can be found in [Kramer \(1958\)](#) and in [Lahey and Moody \(1977\)](#).

Today approximately one third of the operating nuclear power reactors in the United States and one half of the operational nuclear power reactors in Japan are of the BWR design. The largest BWR plants are currently operating with electrical power ratings of slightly over 1400 MWe with a reactor power of approximately 4000 MWth. All US BWRs are GE designs.

BWR overview

GE pursued different design concepts for the earliest Generation I BWRs, that is, natural circulation boilers (Humboldt Bay, Dodewaard), forced circulation boilers (Dresden-1, Big Rock Point, KRB, Oyster Point), and considered nuclear superheat (steam cooled) boilers in development programs to achieve higher levels of electrical power output.

Dresden-1, the first commercial BWR, was a dual-cycle plant that incorporated an external steam drum as well as steam generators ([Fig. 2](#)). This configuration provided a convenient capability to follow load changes. Given an increased load demand, a signal would be sent to the steam generator's control valve to admit additional steam to the lower stage of the turbine, allowing the primary pressure and steaming rate from the reactor to remain unchanged, initially. As steaming rate in the steam generator increased, reactor inlet coolant became more subcooled causing a reduction of in-core steam void formation and higher moderation of neutrons, which in turn caused an increase in reactor power to meet the new load requirement. While this provided a load following advantage, it came at additional plant capital cost and maintenance expense. Therefore, other means of load following (i.e., varying core recirculation flow rate) as well as improved means for steam separation (i.e., in-vessel steam separators and dryers) were developed.

During the 1950s and into the 1960s, when the BWR was in its infancy, it grew by exploring different options and design configurations and feeding back operating experience gained. As a result, standardization did not exist to the extent that it would for future product lines of the Generation II reactors. While the various Generation I BWR configurations successfully operated for many years, operating experience along with improvements in manufacturing capabilities eventually drove toward forced circulation, internal vessel steam separation, and direct-cycle BWRs as a standard configuration.

Fig. 1 Vallecitos BWR plant cutaway. Kramer AW (1958) *Boiling Water Reactors*. Addison-Wesley Publishing Company Inc.

Fig. 2 Dresden-1 schematic diagram. Lahey Jr. RT and Moody FJ (1977) *The Thermal-Hydraulics of a Boiling Water Nuclear Reactor*. Prepared under the American Nuclear Society for United States Energy Research and Development Administration.

With the growth of nuclear power electrical generation worldwide during the 1960s and the following decades, improved BWR product lines—designated as BWR/2, BWR/3, BWR/4, BWR/5 and BWR/6—evolved to meet demand. The Oyster Creek BWR/2 was the first modern plant characterizing the distinctive characteristics of the Generation II BWRs: direct-cycle, forced circulation, internal steam separation and higher power output. **Fig. 3** illustrates these distinctive BWR characteristics for the BWR/6. Additional information about the BWR/6, beyond what is found in this encyclopedia chapter, can be found in the BWR/6 General Description of a Boiling Water Reactor ([General Electric \(GE\) Nuclear Energy Group, 1980](#)).

Fig. 3 Direct cycle BWR (typical of BWR/6). General Electric (GE) Nuclear Energy Group (1980) BWR/6 general description of a boiling water reactor. Revised September 1980.

Key motivators for evolution of the Generation II product lines included emerging safety regulations and improved performance and economic expectations. In the descriptions to follow, key features that distinguish the Generation II BWRs from these perspectives are described.

Generation III designs incorporate evolutionary improvements in areas of safety, performance, efficiency, technology and standardization relative to design and experience of the typical Generation II operating fleet. The ABWR is an example of a BWR Generation III reactor that is being actively pursued worldwide. International BWR development is discussed in a later section.

The primary design objectives during the ABWR development were: improve operation and maintenance; improve safety with diversity; employ advanced technology; reduce construction time; and reduce power generation costs. Key design features that achieved these objectives included fine motion control rod drives, reactor internal pumps, optimized Emergency Core Cooling Systems (ECCS), digital instrumentation and controls, and a reinforced cylindrical concrete containment vessel with a steel liner. Additionally, automated maintenance tools and radiation reduction features contributed to operation and maintenance improvements. The ABWR electrical output is approximately 1350 MWe. Additional information about the ABWR, beyond that which is found in this encyclopedia chapter, can be found in the ABWR Plant General Description (GE-Hitachi Nuclear Energy, 2007). A more complete description of the ABWR can be found in Chapter 1 of the ABWR Design Control Document (GE-Hitachi Nuclear Energy, 2016).

Table 1 shows typical BWR system operating parameters for the ABWR, one BWR/6 and one BWR/5.

Emergency core cooling systems (ECCS)

Early BWRs were designed without separate safety systems to provide core cooling in an emergency, although they did make use of highly reliable feedwater systems for that purpose. However, as concerns were raised with respect to providing adequate core cooling during a Loss-of-Coolant-Accident (LOCA) event that is severe enough to threaten containment integrity, it was required that all nuclear plants must have ECCS. Separate ECCS was included in the BWR/2, and some forms of ECCS were also retrofitted for BWR/1s (Mehta and Pappone, 2009). For BWRs, an ECCS network typically consists of both high and low pressure coolant makeup systems, the use of selected safety-relief valves as part of an Automatic Depressurization System (ADS) to reduce reactor pressure rapidly when necessary to allow injection of low pressure coolant makeup, and supporting systems (e.g., water source, electrical, instrumentation) that are required for proper functioning of the ECCS. High pressure ECCS coolant makeup systems are designed to inject coolant flow into the Reactor Pressure Vessel (RPV) quickly, and can often prevent the need for a rapid reactor

Table 1 Typical GE BWR system parameters.

<i>Design</i>	<i>ABWR 278–872</i>	<i>NMP-2 BWR/5 251–764</i>	<i>Grand Gulf BWR/6 251–800</i>
Rated power (MWth)	3926	3323	3833
Nominal steam dome pressure (psia)	1040	1020	1040
Steam flow rate (Mlbm/h) at 420 °F feedwater temperature	16.843	14.263	16.491
Feedwater flow rate (Mlbm/h)	16.807	14.564	16.455
Core coolant flow rate (Mlbm/h)	115.1	108.5	112.5
Feedwater temperature (°F)	420	420	420
Core average exit quality (% steam)	14.5	13.1	14.6
Number of fuel assemblies	872	764	800
Core weight as UO ₂ (lbm)	379,221	265,551	365,693
Core diameter (equivalent) (in.)	203.3	160.2	191.5
Core height (in.)	146	146	150

depressurization for less severe events. Low pressure ECCS coolant makeup systems must wait for reactor pressure to be substantially reduced, either by the break or the operation of the ADS, in order to begin injecting coolant flow into the RPV.

For the BWR/3 and BWR/4, two electrical divisions of ECCS and an ADS were carried forward from the BWR/2. The two divisions contained three ECCS pumps each, consisting of two Residual Heat Removal (RHR) pumps that were also used for Low Pressure Coolant Injection (LPCI) and one Low Pressure Core Spray (LPCS) pump. A steam turbine driven High Pressure Core Injection (HPCI) systems was also included in the ECCS network. Some later BWR/4 projects (e.g., Limerick Generating Station, Hope Creek Nuclear Generating Station) added a third and fourth electrical division for increased redundancy and redistributed the loading of the ECCS pumps among the increased number of divisions.

At the time the BWR/2, BWR/3, and BWR/4 ECCS were designed, there were no regulations defining the ECCS performance acceptance criteria. In 1973, US 10 CFR 50.46 was issued, which defined the ECCS performance acceptance criteria, for example, the peak cladding temperature was limited to approximately 1200 °C.

Improvement of ECCS continued in the BWR/5 and BWR/6 product lines, with three electrical divisions. Two divisions contained two ECCS pumps each, an RHR pump that was also used for LPCI, and either an LPCS or a second LPCI pump dedicated to reactor vessel coolant injection. The third electrical division consisted of a High Pressure Core Spray (HPCS) system powered by a dedicated diesel generator. The HPCS system replaced a turbine-driven HPCI used in the earlier product lines.

A three divisional ECCS was adopted for the ABWR as shown in Fig. 4. Each division provides both low pressure and high pressure coolant makeup capability and incorporates its own emergency diesel generator power supply. One division includes a Reactor Core Isolation Cooling (RCIC) high pressure makeup system and a Residual Heat Removal/Low Pressure Flooder (RHR/LPFL) low pressure system, while the other two divisions include High Pressure Core Flooder (HPCF) and RHR/LPFL trains. RCIC employs

Fig. 4 ABWR ECCS network. GE-Hitachi Nuclear Energy (2007) The ABWR plant general description. Revised July 1, 2007. https://nuclear.gepower.com/content/dam/gepower-nuclear/global/en_US/documents/ABWR%20General%20Description%20Book.pdf.

a turbine-driven pump feed by reactor steam to provide high pressure makeup when the reactor is isolated from the normal power cycle, drawing water from either the containment Suppression Pool or the Condensate Storage Tank (CST). As with previous BWR product lines, the ABWR also incorporates an Automatic Depressurization System (ADS) to provide effective makeup from the low pressure pumps over the full range of potential LOCA break sizes.

The internal recirculation pumps in the ABWR eliminated the large external recirculation loop piping. By eliminating this piping and the associated large vessel nozzles below the top of the active fuel, it became possible to design the ECCS with less capacity and to keep the core covered during a design basis LOCA.

Containment

Reactor containment systems (Sharpe, 2021) are primarily designed to contain reactor coolant losses from a LOCA event within the containment, which in turn minimizes any potential release of radioactive material to the environment. There are two primary types of reactor containments, dry and wet. A dry reactor containment is sized to remain below design pressure after absorbing all the energy release from a LOCA in its air volume. A wet containment is designed to direct most of the steam released from the reactor during a LOCA through a pool of water (i.e., suppression chamber or suppression pool) that condenses the steam, thereby reducing the containment volume that is necessary to absorb the energy from the coolant release.

The initial BWR containment systems were constructed from steel in a spherical shape, and were dry. However, this was soon superseded by the Mark I, Mark II and Mark III pressure suppression containments, each incorporating a suppression chamber containing a large pool of water.

There are several advantages of an in-containment pressure suppression pool for the BWR:

- Provision of a heat sink for LOCA blowdown steam, safety/relief valve discharge steam, and reactor steam discharged from turbine driven pumped water make up systems;
- Provision of a secure source of coolant water for ECCS and reactor isolation make up and cooling pumps;
- Provision to filter and retain fission products that may be released during an accident or transient event.

Because the BWR may discharge steam when the reactor is isolated during Anticipated Operational Occurrences (AOOs) that pressurize the direct cycle, it was a natural fit for the BWR to adopt the pressure suppression system. This also allowed a smaller containment vessel than a dry containment by taking advantage of the pressure reduction from the suppression pool.

Early BWR product lines utilized the Mark I containment vessel, which consisted of an inverted “light bulb” shaped drywell surrounding the Reactor Pressure Vessel (RPV), and a suppression chamber consisting of a steel pressure vessel with a toroidal shape (“torus”) and a large body of water inside with large surface area for venting steam (Fig. 5).

Fig. 5 Mark I containment configuration. Courtesy GE-Hitachi Nuclear Energy.

The Mark II containment vessel was introduced for some BWR/4s and for BWR/5s, and consisted of a steel dome head and either a post tensioned concrete wall or reinforced concrete wall standing on a base mat of reinforced concrete. The inner surface of the containment was lined with a steel plate to provide a leak tight membrane. The Mark II design provided better access to piping and equipment in the drywell, a simpler vent configuration using straight pipes, the potential to use different construction materials, and a smaller reactor building (Fig. 6).

The Mark III containment vessel was used for the BWR/6 product line and adopted the simpler geometry of a right circular cylinder, which was easier to construct and provided better access to equipment for maintenance. It could be built as either a free-standing steel containment surrounded by a concrete shield building or as a concrete pressure vessel with a liner (Fig. 7).

The ABWR cutaway showing the reactor building, control building and turbine building, consistent with the US certified design, is illustrated in Fig. 8. The Reinforced Concrete Containment Vessel (RCCV) is cylindrical and consists of a top slab, a shell and a foundation. The RCCV is divided into a drywell and a suppression chamber by the diaphragm floor and the RPV pedestal. The compact structure and reactor building integration improves seismic stability and resistance and provides construction and cost effectiveness.

Reactor pressure vessel and internal assembly

Elimination of steam generators in Generation II BWRs resulted in considerable simplification of the BWR Nuclear Steam Supply System (NSSS). Early prototypes and commercial BWRs demonstrated that radiation levels in the Turbine Island (TI) for a direct-cycle BWR were manageable. More shielding is required for the BWR TI, and the Reactor Pressure Vessel (RPV) is larger than that for a Pressurized Water Reactor (PWR), but these increased costs are offset by elimination of steam generators and application of smaller volume pressure suppression containments.

The BWR RPV is larger than the PWR RPV for two reasons: (1) the BWR core operates at a lower power density than the PWR core; and (2) the BWR incorporated steam separators and dryers within the RPV, eliminating the external steam generators and steam drum and greatly reducing in-containment piping to these components characteristic of the earlier dual-cycle BWRs.

Fig. 9 shows the BWR/6 RPV assembly, with details of the steam separator and dryer assemblies illustrated in Fig. 10. Steam rises into the separators whereby it impinges on fixed vanes that spin the steam-water mixture to establish a vortex wherein centrifugal forces separate water from the steam in each of three stages. The steam dryer assembly, mounted above the steam separators, receives steam exiting from the separators, impinging on dryer vanes where residual moisture is collected and drained through a series of troughs to the recirculation downcomer annulus between the core shroud and RPV wall.

The ABWR reactor assembly, illustrating the coolant flow path through the reactor internal pumps, is shown in Fig. 11.

Fig. 8 ABWR cutaway of reactor building, control building and turbine building. GE-Hitachi Nuclear Energy (2007) The ABWR plant general description. Revised July 1, 2007. https://nuclear.gepower.com/content/dam/gepower-nuclear/global/en_US/documents/ABWR%20General%20Description%20Book.pdf.

Fig. 9 BWR/6 reactor assembly. General Electric (GE) Nuclear Energy Group (1980) BWR/6 general description of a boiling water reactor. Revised September 1980.

The ABWR has adopted improvements in design and fabrication of the Reactor Pressure Vessel (RPV) relative to earlier BWR product lines. Earlier RPVs were constructed from welded low alloy carbon steel rolled plate. The ABWR uses low alloy carbon steel forged shell rings at and below the core elevation, thereby avoiding welds in high fluence locations in the core beltline. Shell rings above the core beltline region may be made of low alloy carbon steel forged rings or welded plate.

The bottom head consists of a spherical bottom cap, made from a single forging, extending to encompass the Control Rod Drive (CRD) penetrations and a conical transition section to a toroidal knuckle between the bottom head and vessel shell, also made from

Fig. 10 BWR/6 steam separator and dryer. General Electric (GE) Nuclear Energy Group (1980) BWR/6 general description of a boiling water reactor. Revised September 1980.

a single forging. This eliminates bottom head welds within the CRD pattern. Penetrations are included for the Reactor Internal Pumps (RIPs), and the RIP motor casings are welded to the vessel bottom head.

The vessel support skirt has a conical geometry and is attached to the lower vessel cylindrical shell course. The support skirt attachment is an integral part of the vessel shell ring. Steel anchor bolts extend from the RPV pedestal through the flange of the skirt to secure the support skirt with the pedestal.

To minimize the number of main closure bolts, the ABWR RPV has an inside type flange. This flange allows a hemispherical head closure with a radius less than the vessel radius, which helps minimize the weight of the head closure. The vessel closure seal consists of two concentric "O" rings.

The steam outlet nozzles incorporate a flow restricting venturi. This provides for steamline flow and steamline break detection, and serves as a flow-choking device to limit blowdown and associated loads on the RPV and internals in the event of a postulated main steamline break.

Fig. 11 ABWR reactor assembly and coolant flow path. GE-Hitachi Nuclear Energy (2007) The ABWR plant general description. Revised July 1, 2007. https://nuclear.gepower.com/content/dam/gepower-nuclear/global/en_US/documents/ABWR%20General%20Description%20Book.pdf.

The feedwater nozzles utilize double thermal sleeves welded to the nozzles. The double thermal sleeves protect material of the vessel nozzle inner bend radius from the effects of high frequency thermal cycling that could result from 216 °C (420 °F) feedwater being introduced into the higher temperature saturated fluid inside the RPV. If not mitigated by the double thermal sleeves, rapid cycling of surface temperature at the RPV nozzles could eventually lead to localized material fatigue damage that would shorten the life of the RPV.

In the United States, reactor pressure vessels have been designated as Safety Class 1, in accordance with ASME Code Section III Design Basis. Specifically, Part 50 of the US Code of Federal Regulations, Title 10 (10 CFR 50) regulates the construction of nuclear power plants. Section 10 CFR 50.55(a) defines the reactor vessel to be part of the reactor coolant boundary and requires that the vessel meet the requirements contained in the ASME Boiler and Pressure Vessel Code Section III for Class 1 vessels.

This code deals generally with specified loading conditions in the equipment specification. The specification identifies the design conditions and operating conditions (normal conditions, upset conditions, emergency conditions, faulted conditions and testing conditions). The code further addresses stresses and stress limits to be considered in the analysis of the component. The methods of analysis and stress limits depend upon the category of loading conditions, that is, the requirement for normal conditions are considerably more stringent than those for faulted conditions. Finally, special requirements are given that have to be met by Class 1 vessels, including provisional thickness requirements for shells, reinforcement requirements for nozzles and recommendations for welding nozzles, for example.

The German reactor vessel designs follow the German KTA standards for LWRs. The KTA requirements are very similar to those in the ASME code regarding the definition of stress intensities and allowable stresses, although differences exist in the design requirements for Upper Shelf Energy (USE) and mid-thickness tensile and Charpy values, as well as for in-service inspections.

The RPV is the most critical component susceptible to brittle fracture failure due to irradiation damage from the neutron fluence. In order to avoid conditions wherein brittle fracture is avoided with ample safety margin, a limit is set on the set of Pressure-Temperature that the RPV is allowed to experience. The ASME Boiler & Pressure Vessel Code Sec. XI and 10 CFR 50 Appendix G provide the requirements for deriving the Pressure-Temperature limit curve. When the Pressure-Temperature limit curve is derived in this way, the area of interest (and postulated crack initiation location for the fracture mechanics evaluations) is the beltline of RPV, which directly surrounds the effective height of active core. This is because almost all RPVs have a semi-spherical bottom head shape, making the distance between core and beltline shorter than the distance between core and bottom head. Thus, the beltline is the high neutron fluence area, and therefore, the most susceptible region of the RPV to brittle fracture failure. Monitoring of the material condition through the use of material sample coupons are used to assess fluence effects for this beltline area. In

addition, the neutron fluence characteristics for the RPV and other reactor internal components are evaluated and maintained throughout the life of the reactor.

Reactor core and fuel assemblies

Although different fuel designs and materials were considered during early BWR development, including flat plates and stainless steel clad fuel elements, Dresden-1 set a trend for the BWR by deploying low enriched uranium dioxide pellets encased in Zircaloy-2 tubes arranged in a 6×6 lattice. The fuel bundle lattice was enclosed within a Zircaloy-2 channel to complete the fuel assembly for loading into the reactor. The interior core layout consisted of repeating cells of four fuel assemblies surrounding a boron steel cruciform control rod (Fig. 12). In order to accommodate the control blade, the gap between fuel channel exterior walls adjacent to wings of the cruciform control rod was wider than the gap for channel walls that were not adjacent to a control rod.

As the BWR product line evolved, the core and fuel design also evolved. The original Dresden-1 core layout ("D-lattice") with its non-uniform gap width evolved to a centered lattice ("C-lattice") and BWR six lattice ("S-lattice") with uniform gap and 6 in. [15.2 cm] fuel pitch (distance from fuel assembly centerline to the adjacent fuel assembly centerline) (Fig. 13). The fuel lattice evolved to 7×7 , 8×8 , 9×9 and 10×10 fuel rod arrays, with progressively smaller diameter fuel rods. Initially, the BWR fuel assembly consisted of a uniform enrichment without burnable poisons, but enrichment variation, rod to rod and axially within a rod, addition of burnable poison (gadolinia) in select fuel pellets, and replacement of some fuel rods with water rods to improve neutron moderation were introduced to improve performance and fuel cycle economics.

The introduction of axially varying enrichment and gadolinia concentrations in the BWR core was effective to flatten power distributions and excess reactivity during the fuel operating cycle, reducing the amount of control rod movement needed to compensate for fuel burnup. Generally, only a small fraction (25% or less) of control rods are required to control excess reactivity during operation. A Control Cell Core loading strategy was introduced that loaded lower reactivity fuel around control rods used for power adjustments, reducing a need for periodic control rod exchanges.

Additionally, the use of adjustable flow recirculation systems to change core flow and power further simplified load adjustments in the BWR. Increasing core flow sweeps steam voids from the core to provide added reactivity as a result of the negative designed void reactivity coefficient. Reducing core flow results in higher void fractions in the core and subsequent reduced core power. Using core flow for load following adjustments provides smoother, global changes in core power output, and provides a means of spectral shift (i.e., lower flow, harder neutron spectrum during the cycle, higher flow, softer spectrum toward end of cycle) to improve fuel cycle economics.

As noted above, BWR power density is lower than that for the PWR. Lower power density coupled with lower operating pressure provides operating thermal margin for the BWR, and optimization of power density, core flow and operating pressure provides nuclear-thermal-hydraulic stability during operation of the BWR. A benefit of lower power density is less buildup of Xenon-135 that absorbs neutrons and reduces core reactivity, facilitating lower enrichment requirements and improved fuel utilization than would be the case if power density were higher. Low power density coupled with void reactivity feedback in the BWR also provides strong damping of Xenon transients. However, lower power density of the BWR does result in a larger diameter core and fuel loading inventory than would be the case if power density were higher.

Fig. 12 Dresden-1 interior core arrangement. Kramer AW (1958) *Boiling Water Reactors*. Addison-Wesley Publishing Company Inc.

Fig. 13 BWR/6 fuel assemblies and control rod cell. Courtesy GE-Hitachi Nuclear Energy.

Control rod drive system

Dresden-1 employed bottom mounted, hydraulic Locking Piston Control Rod Drives (LPCRD) that set a trend for the Generation II BWR product lines. The Control Rod Drive (CRD) system provides controlled, notched rod movement and positioning for power shaping and burnup compensation, as well as rapid full insertion of all control rods for reactor trip (SCRAM).

Typically, a notch was discrete movement of 6 in. [15.2 cm] for the Generation II BWRs. The control rod was moved by applying pressure greater than reactor pressure to either the top or bottom of a main drive piston. The control rod was held at a given position by a collet engaging one of several notches in an index tube (Figs. 14 and 15). An accumulator provides hydraulic pressure greater than reactor pressure. Loss of electrical power to the system or reduction of accumulator pressure results in opening of scram pilot valves, thereby effecting rapid shutdown of the reactor.

The ABWR diversified the CRD to incorporate fine motion of control rods with an electric motor for normal operations, while retaining and simplifying the hydraulic scram (Fig. 16). Because the Fine Motion Control Rod Drive (FMCRD) has the additional electrical motor, it drives the control blades into the core even if the primary hydraulic system fails to do so, providing additional capability to hydraulic insertion of the control rods. The drive also includes safety enhancements against rod run out (electromechanical brake) and rod ejection (internal restraint) (see Fig. 16).

Fig. 14 BWR/6 locking piston hydraulic drive. General Electric (GE) Nuclear Energy Group (1980) BWR/6 general description of a boiling water reactor. Revised September 1980.

Recirculation system

The initial Generation II BWRs used five external recirculation loops with pumps to provide forced recirculation coolant flow through the core. Subsequently, an internal jet pump design was developed that reduced the number of external loops to two. The recirculation pumps take suction from downward flow in an annulus between a core shroud and the vessel through two recirculation nozzles. The water is pumped to higher pressure and distributed through a manifold to which a number of riser pipes are connected, that return flow through vessel inlet nozzles to be discharged to a jet pump throat. Through a momentum exchange

Fig. 15 BWR/6 locking piston hydraulic drive system. General Electric (GE) Nuclear Energy Group (1980) BWR/6 general description of a boiling water reactor. Revised September 1980.

Fig. 16 ABWR fine motion control rod drive. GE-Hitachi Nuclear Energy (2007) The ABWR plant general description. Revised July 1, 2007. https://nuclear.gepower.com/content/dam/gepower-nuclear/global/en_US/documents/ABWR%20General%20Description%20Book.pdf.

process, this flow induces surrounding water in the downcomer region to be drawn into the throat where the flows mix, diffuse into a diffuser, and finally are discharged into a lower core plenum. This recirculation system is illustrated in Fig. 17.

With the jet pump recirculation system, it became possible to reflood the core region of the vessel up to the top of the jet pump. This also provided an ECCS safety improvement, in that no recirculation line break could prevent reflooding of the core up to this level.

The ABWR design includes 10 Reactor Internal Pumps (RIPs) whose diffusers and impellers are arranged circumferentially between the shroud and the RPV near the RPV bottom head and whose motors are installed in the motor casing at the bottom of the RPV (Fig. 18). The RIPs function collectively to force the reactor coolant through the lower plenum of the reactor and upward through openings in the fuel support, upward through the fuel assemblies and steam separators, and down into the annulus to be mixed with feedwater and recirculated through the core. The RIPs are variable speed to adjust core flow. A change in RIP speed conditions will vary the core flow in the reactor, which, in turn, will change the reactor power during normal power range operation.

Ancillary BWR components

BWR power plants also contain components that are required to maintain normal operation of the plant, and to mitigate consequences during accidents.

Fig. 17 BWR/6 jet pump recirculation system. General Electric (GE) Nuclear Energy Group (1980) BWR/6 general description of a boiling water reactor. Revised September 1980.

The BWR design includes uses a Feedwater Control System (FWCS) to maintain water level control within the RPV. The FWCS returns condensed steam back to the RPV and provides makeup water as needed in case of any inventory losses.

The BWR design includes a Reactivity Control System (RCS) to control movement of control rods during normal operation and in response to anticipated operational occurrences and accidents. The RCS initiates a reactor scram on a variety of signals (e.g., high neutron flux, closure of all Main Steam Isolation Valves, low reactor water level).

Reactor pressure is maintained during plant operation using a Pressure Control System (PCS). The PCS controls the positions of the turbine control valves to maintain a constant turbine inlet pressure for GE BWRs. The ASEA Atom BWRs typically use the PCS to maintain a constant steam dome pressure in the RPV.

In the event of a failure of the control rods to insert when needed, the BWR uses a Standby Liquid Control (SLC) system to inject a sodium pentaborate solution into the RPV. The boron in this solution is a neutron absorber, and the SLC system is sized to be able to bring the plant to cold shutdown without control rod insertion.

Radioactive Waste Management Systems are also included in the BWR design to process solid, liquid and gaseous sources of radiation such that offsite doses to the public remain below acceptable limits.

Balance of plant components

Balance of Plant Systems (Arcaro, 2021) for a BWR are functionally the same as those used in fossil steam plants. Major differences between Balance of Plant Systems for a BWR and a fossil steam plant are:

- a. Due to the continuous production of decay heat in the reactor core even while in shutdown, the shutdown cooling mode of the Residual Heat Removal system must remain in operation. No cooling is needed for a fossil plant during shutdown.
- b. The BWR delivers a high flow of low temperature saturated steam whereas a fossil plant delivers a smaller flow of superheated steam. This requires a "wet turbine" design, which has a different turbine blade design than those used in a fossil turbine that accepts superheated steam and results in lower energy conversion efficiency because of the lower turbine inlet temperature.

Operation of BWR

Today most BWRs are operated as large (800–1300 MWe) base load units which are maintained at or near full power conditions during their entire operating cycle (Young, 2021). Most US BWRs operate on a 24-month refueling schedule with a few plants on 18-month refueling schedules. Non-US BWRs generally operate on a 12-month refueling schedule, although there are exceptions.

Fig. 18 ABWR reactor internal pump. GE-Hitachi Nuclear Energy (2007) The ABWR plant general description. Revised July 1, 2007. https://nuclear.gepower.com/content/dam/gepower-nuclear/global/en_US/documents/ABWR%20General%20Description%20Book.pdf.

BWRs start an operating cycle with a mixture of partially and fully withdrawn control rods, then periodically withdraw the partially inserted control rods as needed to remain at rated power conditions. Core excess reactivity is also controlled by a burnable absorber (gadolinium) that is located in several fuel rods in each fuel assembly.

International BWR development

While the BWR prospered in the United States, BWRs were constructed in Mexico, Europe and Asia as well. In Europe, BWRs were constructed from the product lines described above in the Netherlands, Italy, Spain, Switzerland, and Germany. In Germany, Kraftwerk Union AG (founded by AEG and Siemens, and subsequently integrated into Areva) further advanced the design of the earlier imported BWRs of GE design, culminating with the construction of the Gundremmingen Nuclear Power Plant Units B and C. Features of these units included fine motion control rod drives, internal recirculation pumps, a three train full-range residual heat removal system and a pre-stressed cylindrical concrete containment with steel liner.

In 1947, Sweden established a domestic atomic energy research program that led to the country's first experimental reactor commissioned in 1954. In 1966, a Sydkraft-led consortium (OKG AB) ordered the Oskarshamn 1 BWR from ASEA Atom. This was the first western light water reactor designed and built without requiring a license from US vendors (World Nuclear Association, 2017). Several additional BWRs of increasing output were supplied by ASEA Atom (subsequently Westinghouse Electric Sweden AB, and currently owned by Toshiba Corporation) in Sweden and Finland. The first five ASEA Atom BWRs were similar in design to the GE BWR/2 product line. The last six ASEA Atom BWRs introduced fine motion control rod drives and internal recirculation pumps in their reactor design.

In Asia, BWRs were constructed from the product lines described above in Japan, India and Taiwan. India constructed two BWR/1 units at the Tarapur Atomic Power Station.

Several commercial BWRs were constructed of the BWR/2, BWR/3, BWR/4 and BWR/5 types with Mark I and Mark II containments in Japan, the first being Tsuruga Unit 1. Cooperative programs among the designers, GE, Hitachi and Toshiba introduced further improvements for the BWR in Japan, culminating with the construction of the Advanced Boiling Water Reactor (ABWR) at Tokyo Electric Power Company's Kashiwazaki-Kariwa Nuclear Power Station.

To develop the ABWR design, an Advanced Engineering Team (AET) was formed in the late 1970s to review design, construction and operating experiences in Japan, the United States and Europe. The AET consisted of a 25-member-team with representatives from a world-wide range of technology suppliers such as General Electric (United States), Hitachi and Toshiba (Japan), ASEA-Atom (Sweden) and Ansaldo (Italy). Architect engineering support was provided by NUCON of the Netherlands and Bechtel and Ebasco from the United States. The AET effort was completed in 1979.

Future of the BWR

To date, two standardized US BWR designs (ABWR and ESBWR) with thermal power ratings up to 4500 MWth have been approved through the USNRC's 10 CFR 52 design certification process for US applications (Ray, 2021). The ABWR design certification is currently undergoing a renewal review by the USNRC. A third standardized US BWR design (BWRX-300) is currently undergoing design certification review by the USNRC.

The ABWR design is currently offered by three companies: GE-Hitachi Nuclear Energy, Hitachi-GE Nuclear Energy, and Toshiba. While there are some differences in the three companies' designs, and some differences that are location specific, as mentioned above for the UK ABWR, the descriptions above have focused on key common similarities between the designs that provide a general description of ABWR.

Supplementary characteristics suggested for Generation III+ plants are simplicity and improved economics. GE-Hitachi's Economic Simplified Boiling Water Reactor (ESBWR) design, which incorporates several passive safety systems with a reduction of active components exhibits these characteristics, as well as the characteristic of improved safety. Although not yet constructed, the ESBWR is under active consideration for construction in the United States, and has also been proposed for construction in other countries. Two US utilities have received NRC approval for a Combined License that would allow them to construct the ESBWR on their approved sites. Additional details about the ESBWR are provided in the following section.

The BWRX-300 is a ~300 MWe water-cooled, natural circulation Small Modular Reactor (SMR) with passive safety systems, which represents the simplest, yet most innovative BWR design since GE began developing nuclear reactors in 1955. The BWRX-300 is based on the US NRC-licensed, 1520 MWe ESBWR and is designed to provide clean, flexible baseload electricity generation that is competitively priced and estimated to have the lifecycle costs of typical natural gas combined-cycle plants. Additional information about the BWRX-300 can be found on the [GE-Hitachi Nuclear Energy, n.d.](#) website referenced in the bibliography.

International cooperative efforts have led to today's Generation III/III+ BWR designs with improvements in safety, operation and maintenance, construction and economics. The Boiling Water Reactor is well positioned to serve in conjunction with the current operational fleet as well as emerging Generation IV reactor designs of the future.

ESBWR

The ESBWR is designed as a large-size reactor, approximately 1500 MWe, with natural circulation adopted for core coolant recirculation. The core height is reduced relative to ABWR, which reduces core pressure drop, and a "chimney" is placed in the two-phase flow region above the core to enhance driving head for natural circulation flow. Elimination of recirculation pumps also reduces pressure drop in the natural circulation flow circuit.

The ESBWR RPV is taller than the ABWR RPV with the addition of the "chimney" above the core, but the large vessel volume provides a mild response to transients. The larger steam volume during normal operation leads to a slower and lower pressure rise for pressurization transients. In order to provide enhanced margin to keep the core covered with water using the passive GDCS for LOCA events, the ESBWR core is located lower in the RPV than the ABWR core.

The number of fuel assemblies for ESBWR is increased while remaining within the RPV diameter limit established by the ABWR. Modifications were also made to the steam separator assembly based on additional test data. The US certified ESBWR design introduced 10 × 10 fuel with part length fuel rods and improvements in analytical methods, for example, the Transient Reactor Analysis Code-GE (TRACG) to assess reactor natural circulation, transient and accident conditions. Load following capability was enhanced by providing feedwater temperature control. The resulting reactor assembly is illustrated in [Fig. 19](#).

The ESBWR Passive Safety Systems are illustrated in [Fig. 20](#). The ESBWR incorporates four redundant mechanical trains of passive Gravity-Driven Cooling System (GDCS), an Automatic Depressurization System (ADS), and a Passive Containment Cooling System (PCCS). Heat removal and inventory addition are also contributed by the Isolation Condenser (IC) System and the Standby Liquid Control (SLC) System, with the latter providing reactor core shutdown as well. All mechanical trains of the passive safety systems are designed to remain operable even if one electrical division fails and another division is out of service for maintenance.

Fig. 19 ESBWR reactor assembly. GE-Hitachi Nuclear Energy (2011) The ESBWR plant general description. Revised June 1, 2011. https://nuclear.gepower.com/content/dam/gepower-nuclear/global/en_US/documents/ESBWR_General%20Description%20Book.pdf.

High pressure inventory control and heat removal is accomplished with the use of the IC System if the reactor becomes isolated from the normal heat sink. The IC System initiates without dependence on AC power, either off-site or on-site. Elevation differences between the IC heat exchanger and RPV provide gravity driven natural circulation flow. The IC pool is sized to provide 72 h of heat removal before refilling, and beyond 72 h through simple operator action to refill the IC pool using on-site resources, even without the availability of off-site or on-site AC power. The IC System includes provisions to assure that excess hydrogen or air does not accumulate in the IC steam supply line and heat exchanger during either standby or normal IC System operation.

Each train of the GDCS consists of three independent subsystems: a short-term core makeup and cooling (injection) system from the GDCS pool, a long-term cooling (equalizing) connection from the suppression pool, and a deluge line that can provide makeup to the Basemat-internal Melt Arrest Coolability (BiMAC) core catcher, a severe accident feature. The short-term and long-term subsystems provide gravity driven cooling water to replace RPV water inventory lost during a postulated LOCA and subsequent decay heat boil off.

GDCS actuation valves are squib valves, gas propellant shear valves that are normally closed but open when a pyrotechnic booster charge is ignited using DC power. Once the squib valve is actuated, it remains open to provide a flow path to the vessel. Check valves are incorporated in the system design to mitigate consequences against spurious valve initiation. The GDCS check valves remain fully open when zero differential pressure exists across the valve, in order to minimize the potential for sticking in the closed position during long periods of nonuse.

The ADS is automatically initiated if an RPV low water level signal or if high drywell pressure is sustained for specified periods. Redundant trip channels are arranged in divisionally separated logic, such that each Depressurization Valve (DPV) or Safety-Relief Valve (SRV) receives separate initiation signals from three safety-related divisions and also a Diverse Protection System (DPS). Each SRV is initiated by a solenoid valve controlling a pneumatic actuator. Each DPV is initiated by a squib located on the valve. The ADS valve openings are staggered in time to control the blowdown rate and prevent excessive suppression pool swell and reduce dynamic loads.

Fig. 20 ESBWR passive safety systems. GE-Hitachi Nuclear Energy (2011) The ESBWR plant general description. Revised June 1, 2011. https://nuclear.gepower.com/content/dam/gepower-nuclear/global/en_US/documents/ESBWR_General%20Description%20Book.pdf.

The PCCS maintains the containment within its pressure limits for Design Basis Accidents (DBAs). The PCCS consists of six independent trains, each containing a steam condenser. The PCCS heat exchangers receive steam-gas mixture supply directly from the containment drywell, driven by pressure difference created between the drywell and the suppression pool during LOCA. Steam condensed in the PCCS heat exchanger tubes is returned to the GDSC pool by gravity, and subsequently to the RPV. Gases are returned by a vent line to the suppression pool airspace. Together with the pressure suppression containment, the PCCS condensers limit containment pressure to less than its design pressure for 72 h after a LOCA with makeup to the IC/PCC pool, and beyond 72 h with pool makeup and PCCS vent fan operation.

The PCCS vent fans aid in long-term removal of non-condensable gas from the PCCS condensers for continued condenser efficiency. The discharge of each PCCS vent fan is submerged in the GDSC pool drain pan to prevent backflow that could otherwise interfere with the normal venting of the PCCS. The fans are manually initiated by operator action and are powered by an ancillary diesel generator.

The SLC System provides a backup method to bring the nuclear reactor to subcriticality and to maintain subcriticality as the reactor cools. It is automatically initiated in case of signals indicative of LOCA or Anticipated Transient Without SCRAM (ATWS). The SLC System is a passive system incorporating two identical and separate trains using pressurized accumulators to inject borated water rapidly and directly in the bypass volume of the core.

The ESBWR cutaway showing the Reactor Building, Fuel Building, Control Building and Turbine Building, consistent with the US certified design, is illustrated in Fig. 21. The Reinforced Concrete Containment Vessel (RCCV) is cylindrical and consists of a top slab, a shell incorporating a raised suppression pool, lower drywell and supporting foundation, and is integrated with the Reactor Building to improve seismic stability and resistance. The Reactor Building is designed to provide a secondary containment. The IC/PCC pools, consisting of inner and outer replenishing pools, are located above the RPV in the Reactor Building. To provide for IC/PCC volume in the reactor building, the spent fuel pool is located in a Fuel Building adjacent to the Reactor Building and shares a common basemat. Fuel is transported to the spent fuel pool using an Inclined Fuel Transfer System.

Additional information about the ESBWR can be found in the ESBWR Plant General Description (GE-Hitachi Nuclear Energy, 2011).

Glossary

Criticality The constant-power operating condition of a reactor, in which nuclear fuel sustains a steady-state fission chain reaction. A reactor achieves criticality (and is said to be *critical*) when neutrons released in a fission event induce exactly one other fission.

Reactivity A measure of a reactor's departure from criticality. A reactor with positive reactivity is said to be *supercritical* and its power increases. A reactor with negative reactivity is said to be *subcritical* and its power decreases.

Introduction

Heavy-water reactors (HWRs) are nuclear reactors that are moderated¹ (and, possibly, also cooled) by heavy water. Heavy water, chemical formula D₂O, differs from regular, or light, water, by having two deuterium atoms instead of the usual two hydrogen ones. Deuterium is an isotope of hydrogen whose nucleus contains both a proton and a neutron. Because heavy water has better moderating properties than light water, heavy-water moderated lattices can attain criticality for lower uranium enrichments than light-water ones, including for natural uranium, which has only $\sim 0.7\%$ ²³⁵U.

A substance's moderating properties are expressed by the *moderating ratio*, which captures three of the desirable properties of a moderator: large decrease in neutron energy (increase in neutron lethargy) per collision, large scattering microscopic cross section, and small absorption cross section. The moderating ratio is calculated by taking the product between the average lethargy increment with the scattering cross section and dividing by the absorption cross section. Heavy water has a moderating ratio of ~ 5500 , compared to ~ 70 for light water (see Wietfeldt, 2021).

The high moderating ratio of heavy water is due primarily to heavy water's very low absorption cross section. A consequence of that is that the infinite multiplication constant of a UO₂-heavy-water lattice keeps increasing with the moderator-to-fuel volume ratio up to values of ~ 20 , much higher than the value of ~ 2 in a light-water reactor (LWR). Consequently, HWRs have higher moderator-to-fuel ratios than LWRs and, therefore, generally larger cores for a given power level, implying significantly lower average power densities than LWRs (~ 10 MW/m³ vs. ~ 50 MW/m³). The large amount of heavy water impacts the dynamic properties of HWRs as well. In particular, HWRs have a longer neutron generation time² than LWRs (~ 0.9 ms vs. ~ 0.05 ms) and a small number of additional delayed neutrons³ (~ 0.0003 per fission), in the form of *photoneutrons* resulting from the reaction of gamma rays with deuterium.

In systems where the coolant and moderator are physically separated and where coolant represents only a small fraction of the heavy-water volume in the core, loss of coolant leads only to a marginal decrease in moderation. In such systems, because of the reduction in absorption and because of subtle neutron-spectrum effects, the reactivity of the core increases following loss of coolant unaccompanied by loss of moderator. This effect is mitigated by the long generation time, resulting in slow transients, which can be safely terminated by engineered shutdown systems. As an additional measure of safety, some designs employ two separate shutdown systems.

Because the heavy water is exposed to a high neutron flux, deuterium can absorb a neutron and transmute into tritium, which undergoes beta decay (maximum energy 18.6 keV) with a half-life of ~ 12 years and can be of radiological concern if ingested or inhaled. The tritium activity in the coolant can reach ~ 1.4 Ci/kg (Son et al., 2009). Its release is usually prevented by the use of advanced seal technology for the coolant and moderator systems. Some plants also employ a Tritium Removal Facility (TRF) whereby tritium is separated from tritiated heavy water by catalytic exchange followed by cryogenic distillation, and is subsequently stored as titanium hydride (Son et al., 2009) for subsequent industrial use (e.g., luminescent signs).

High heavy-water purity (less than 1% light water content in moderator) is essential for maintaining good neutron economy. A distillation facility is used to upgrade the isotopic content, as necessary.

Over the years, a number of heavy-water power reactor designs were developed in Canada, the UK, India, Germany and Argentina. The most common is the Canadian CANDU⁴ (CANada Deuterium Uranium) design. There are several variants of the CANDU design, of which the CANDU-6 is the closest to a reference design and also the one with the widest worldwide deployment. This overview of heavy-water power reactors therefore consists of a fairly detailed presentation of the CANDU-6 reactor system and a summary of the other designs and how they differ from the CANDU-6.

The CANDU-6 reactor system

The CANDU-6 reactor is a pressure-tube HWR which uses heavy water as both moderator and coolant. However, the two are physically separated and belong to different circuits. CANDU-6 fuel consists of fuel bundles approximately 0.5 m long. Each fuel bundle

¹Moderation is the process of neutron slowing down, usually by collision with light nuclei.

²The neutron generation time can be interpreted as the average "age" (time since "birth" through fission) of neutrons in a reactor. See also Tsvetkov (2021) and Hamon (2021).

³Delayed neutrons are neutrons emitted after the fission event, as a consequence of fission-product decay. See also Tsvetkov (2021) and Hamon (2021).

⁴CANDU is a trademark of AECL and SNC Lavalin.

Fig. 1 CANDU-6 fuel bundle.

has 37 fuel elements arranged in three concentric rings (6, 12 and 18 elements each) plus a central element (**Fig. 1**). A fuel element consists of UO_2 fuel pellets approximately 1 cm in diameter, encased in a collapsible Zircaloy sheath. The elements forming a bundle are held together by end plates and are prevented from rubbing against each other by spacers. The diameter of a fuel bundle is approximately 10 cm. Fuel-bundle parameters are shown in **Table 1** (IAEA, 2002).

Fuel bundles reside in horizontal pressure tubes made of a Zr-Nb alloy, each holding 12 fuel bundles. It follows that pressure tubes are approximately 6 m long. Heavy water coolant runs through the pressure tubes and cools the fuel during reactor operation. Pressure tubes are arranged in a rectangular array with a pitch of 28.575 cm (a trade-off between excellent moderation and the cost of heavy water) and are immersed in the heavy-water moderator contained in a large, horizontal, cylindrical non-pressurized vessel, called the *calandria*. Unlike the coolant, the moderator is kept at near-atmospheric pressure and $\sim 70^\circ\text{C}$. To avoid heat loss from the hot coolant to the cooler moderator, each pressure tube is surrounded by a slightly-larger-diameter tube (also made of Zr-Nb alloy), called the calandria tube. There is a gas-filled gap between the two tubes which acts as a thermal insulator to prevent heat loss from the coolant to the moderator. The gas can also be monitored for heavy-water vapor which can indicate a crack/leak in the pressure tube, thus allowing preventative measures before a break occurs. The pressure tube and the calandria tube form the fuel channel. Because the pressure tube holds the weight of the fuel, while the calandria tube doesn't, the pressure tube would normally tend to sag and possibly touch the calandria tube. This is prevented by spacers (garter springs) placed at several axial locations between the pressure and calandria tubes. A CANDU-6 reactor has 380 fuel channels and 4560 fuel bundles. A simplified diagram of the CANDU-6 reactor is shown in **Fig. 2**.

CANDU reactors are refueled on-line. New fuel is pushed into the channel at one end and burnt fuel is removed from the channel at the other end. On refueling, fuel is pushed in the same direction as the coolant flow (fueling with flow). While refueling against flow was used at one point in some CANDU units, currently all CANDU units are fueled with flow. Because flow and refueling direction alternate from one channel to the next, CANDU reactors are said to have bi-directional refueling.

Fueling is performed using fueling machines. A refueling operation involves two fueling machines, one at each end of the reactor. The first machine initially contains the fresh fuel, while the second machine is empty. After refueling, the first machine is empty, while the second machine contains the burnt fuel. Each fueling machine consists of a machine head that attaches to the fuel channel, a revolving fuel magazine, and a ram that pushes the fuel into the fuel channel. The refueling operation is automated and computer-controlled.

Table 1 CANDU-6 fuel bundle characteristics.

Fuel material	Natural UO_2
Bundle Weight	24 kg
Uranium Weight per Bundle	19.2 kg
Sheath Outside Diameter (cold)	13.1 mm
Sheath Thickness	0.4 mm
Sheath Material	Zircaloy 4
Elements per Bundle	37
Bundle Length	495.3 mm
Bundle Outside Diameter	102.4 mm

Fig. 2 CANDU-6 simplified reactor diagram.

Primary and secondary circuits

In a CANDU reactor, heavy-water coolant runs through the pressure tubes at high temperature ($\sim 280^{\circ}\text{C}$) and high pressure ($\sim 12\text{ Mpa}$). Coolant in adjacent channels flows in opposite directions, in a checkerboard pattern. Coolant reaches each pressure tube through an inlet *feeder* pipe and leaves it through an outlet *feeder* pipe. Inlet feeders draw their coolant from inlet *headers* and outlet feeders send their coolant to outlet *headers*. A CANDU-6 unit has two separate cooling loops, each comprising 190 channels. Each loop has two passes comprising channels in which coolant flows in the same direction. Each pass also includes a pump on the inlet (cold) side and a steam generator on the outlet (hot) side. The pressure tubes, piping, pumps and steam generators make up the primary circuit, also called the Primary Heat Transport System (PHTS). A simplified diagram of the PHTS is shown in Fig. 3.

A pressurizer controls the pressure in the primary circuit when the reactor is at power. A feed-and-bleed circuit can adjust the coolant inventory when that is made necessary by the change in coolant specific volume during reactor heat-up or cool-down. The pressurizer is isolated from the PHTS at low reactor power and during shutdown. The main parameters of the PHTS are shown in Table 2, adapted from (IAEA, 2002).

The moderator in the calandria vessel is part of a sealed moderator circuit which also comprises a heat exchanger and moderator pump. The heat exchanger is used to remove the moderator heat that comes primarily from gamma radiation emitted during operation. The pressure in the calandria vessel is near atmospheric pressure and four relief pipes are provided, each terminated with a rupture disk designed to break if the moderator pressure increases beyond a prescribed limit.

The secondary circuit, also called the Secondary Heat Transport System (SHTS), is similar to that of a LWR. It consists of the secondary side of the 4 steam generators, steam lines, turbines, condenser and feedwater pump and lines. A simplified diagram of the SHTS is shown in Fig. 4 and its main parameters are shown in Table 3 (IAEA, 2002).

Fig. 3 CANDU-6 simplified PHTS diagram.

Table 2 CANDU-6 PHTS parameters.

Thermal output	2064 MW (th)
Coolant Flow Rate	7700 kg/s
Design Temperature (RIH)	279 °C
Design Pressure (RIH)	12.7 MPa (abs)
Design Temperature (ROH)	318 °C
Design Pressure (ROH)	11.0 MPa (abs)
Number of PHT Pumps	4
Pump Rated Capacity	2228 l/s
Pump Rated Head	215 m
Pressure Tube Inside Diameter	103.4 mm
Core Length	5.94 m
Number of Pressure Tubes	380
Pressure Tube Coolant Flow (nominal)	24 kg/s
Pressure Drop (12 bundles)	758 kPa

Operational considerations

Online refueling

The main method of maintaining core criticality in a CANDU reactor is refueling. CANDU reactors are refueled online. In a CANDU-6 unit, each channel is refueled on average every 6.75 months, which corresponds to almost two refueling operations taking place each day. The standard refueling scheme is a push-trough scheme which replaces 8 of the 12 bundles. However, if a defective bundle needs to be removed, all 12 bundles can be replaced in a single refueling operation.

Between refuelings, core criticality is maintained by 14 Zone-Control Units (ZCUs) which are vertical tubes filled with light water. By slowly decreasing the water level in ZCUs, the core reactivity⁵ is increased to compensate the decrease due to fuel burnup. When a channel is refueled, the water level in ZCUs is increased almost in step fashion. The total reactivity worth of the 14 ZCUs is ~700 pcm.

⁵Reactivity is the relative imbalance between the neutron production rate and the neutron loss rate in the core. It is measured in pcm. One positive pcm corresponds to the situation where the neutron production rate is 0.001% larger than the neutron loss rate. See also Tsvetkov (2021) and Hamon (2021).

Table 3 SHTS parameters (IAEA, 2002).

Number and type of steam generators	4, vertical, inverted U tubes
Total Steam Flow (4 SG)	1033 kg/s
Steam Pressure (full power)	4.7 MPa (abs)
Steam Temperature (full power)	260 °C
Maximum Moisture	0.25%
Feedwater Temperature	187 °C
Number of High-Pressure Turbines	1
Number of Low-Pressure Turbines	3
Energy Conversion Efficiency (gross/net)	35%/33%

From IAEA (2002) Technical Reports Series No. 407, 2002. *Heavy Water Reactors: Status and Projected Development*. International Atomic Energy Agency. Retrieved from: https://www-pub.iaea.org/MTCD/publications/PDF/TRS407_scr/D407_scr1.pdf.

Equilibrium core

When a reactor is initially commissioned, it usually starts with a core full of fresh fuel, which is slightly supercritical. The excess reactivity is compensated by the addition of poison (boron) in the moderator. Poison is slowly removed from the moderator as fuel burns. Fine reactivity control is achieved by the ZCUs. Once all the poison has been removed from the moderator, reactor fueling begins (after ~100 Full-Power Days). As refueling continues, the core properties at each bundle position vary continuously due, on one hand, to fuel burnup and, on the other hand, to continuous refueling. Over a few months, the core reaches a state whereby properties and power at each bundle position vary only little with respect to some average value. Such a core state is known as the *equilibrium core*. The average burnup, average *dwelt time* (inverse of refueling frequency) for each channel and average power distribution in the equilibrium core are found using a *time-average* calculation. By contrast, the burnup and power distribution at any given time are determined from an *instantaneous* calculation based on *core-follow* which accounts for the actual refueling times of each channel and specific instantaneous burnup of each fuel bundle. The core-average discharge burnup at equilibrium is ~7.5 MWd/kg(U). The core is usually divided in two burnup regions, an inner one and an outer one. The inner region has a higher discharge burnup than the outer region in order to achieve a level of power flattening in the core and improve the hot-channel

factor.⁶ The individual average dwell time of each channel depends on its prescribed average discharge burnup and on the average power level in that channel. The average dwell time increases with the former and decreases with the latter. Although the discharge burnup of CANDU reactors is only a fraction of that of LWRs, their fuel utilization is slightly better and, consequently, they consume slightly less natural uranium per unit of generated energy. That is because the ratio of the LWR-to-CANDU discharge burnup is slightly lower than the ratio of the LWR-to-CANDU enrichment. The low CANDU discharge burnup compared to LWR results in a correspondingly larger (~ 6 times) amount of used fuel produced per unit of generated energy.

Daily refueling

While the average refueling frequency for each channel is found using the time-average core model, the practical decisions on which specific channels to refuel in any given week have to account for additional considerations, such as:

1. Time elapsed since a channel's last refueling.
Channels for which this exceeds the time-average dwell time for that channel are prioritized for refueling.
2. Average burnup of last 8 bundles (as determined from an *instantaneous* calculation) in the channels (the ones to be discharged in a refueling operation).
Channels for which this burnup exceeds the time-average discharge-burnup value for that core region are prioritized for refueling.
3. Channel power.
Channels with power lower than the time-average one are given preference.
4. Zone power.
A CANDU-6 core is formally divided into 14 *power zones*. Channels located in a zone whose current power (as determined from an *instantaneous* calculation) is lower than its time-average power are given preference.
5. Overall core power symmetry and closeness to the time-average power distribution.
Preference is given to channels whose refueling ensures overall power symmetry and brings the instantaneous power shape close to the time-average power shape.
6. Resulting change in the ZCU fills.
Following a refueling operation, ZCU fills will adjust automatically both to ensure core criticality and to ensure symmetry of the power distribution. Individual ZCUs will fill to different levels depending on which channels are refueled and how that changes the core reactivity and power distribution. Channels are selected for refueling with an aim to avoid putting excessive demands on the ZCU system as it tries to maintain core criticality and compensate for flux distortions. The goal is to maintain the individual ZCU fills between 20% and 70% and the average ZCU fill between 40% and 60%.

If refueling cannot be performed due to fueling-machine unavailability or any other reason, the core becomes subcritical in less than 1 day. To avoid shutting down the reactor in such circumstances, core reactivity can be increased by removing banks of *adjuster rods* from the core. By sequentially withdrawing banks of adjuster rods, the reactor can be maintained critical for a month without refueling. The reactivity worth of any bank of adjuster rods is slightly smaller than the total reactivity worth of the ZCUs, in order to maintain the latter's ability to keep the core critical. Adjuster rods are *gray* rods made of stainless steel or cobalt that reside in the core during normal operation and also serve as a second means (besides differential discharge burnup) of flattening the power distribution and hence decrease the hot-channel factor. Adjuster rods can also be withdrawn to provide Xe reactivity override,⁷ to allow for reactor restart up to 30 min after a spurious shutdown (subject to regulatory constraints).

Control and safety systems

CANDU-6 reactors have completely separate control and shutdown systems. The control system is known as the Reactor Regulating System (RRS). There are two separate shutdown systems known as SDS1 and SDS2. The RRS consists of a set of routines running on a digital control computer, while shutdown systems employ hard-wired circuitry. The reactor regulating system and the shutdown systems each employ an array of detectors and each operate a series of reactivity devices.

Reactivity devices

CANDU-6 reactors employ six types of reactivity devices, as follows.

- Zone Control Units
Zone Control Units (ZCUs) consist of a vertical tube which can be filled with light water, which acts as a mild absorber.⁸ There are 14 ZCUs, one per power zone. ZCUs are part of the Reactor Regulating System. They serve to maintain core criticality between refuelings, adjust the power level and shape, and effect slow power maneuvers.

⁶The hot-channel factor is defined as the ratio of the maximum heat flux in the core to the average heat flux in the core.

⁷¹³⁵Xe is a fission product and a strong neutron absorber. Its concentration increases temporarily after the reactor is shut down. In order to be able to restart the reactor a short time after it has been shut down, ¹³⁵Xe absorption needs to be *overridden* by removing some other absorbers from the core.

⁸Because of the large amount of heavy water in the lattice, neutrons are already very well thermalized and the addition of light water simply increases absorption, without significantly altering the spectrum.

Fig. 5 Location of CANDU-6 reactivity devices during normal operation. MCAs are shown in blue, ZCUs in light blue, SORs in red, ARs in green, and LINS in fuchsia. Guide tubes are not shown.

- Adjuster Rods

The 21 vertical Adjuster Rods (ARs) are stainless-steel “gray” rods⁹ which are positioned in the core during normal operation, inside guide tubes located between fuel channels in the unpressurized calandria vessel, as shown in Fig. 5. They can be driven in and out of the core using electrical motors. Adjuster rods are part of the Reactor Regulating System.

- Shutoff Rods

The CANDU-6 reactor has 28 vertical Shutoff Rods (SORs), which are “black” rods consisting of cadmium cylinders sandwiched between concentric stainless-steel ones. They are positioned above the core during normal operation, are spring-loaded and can be dropped into the core (with spring assist) inside guide tubes located between fuel channels, in the unpressurized calandria vessel. Shutoff rods are part of SDS1.

- Mechanical Control Absorbers

The CANDU-6 reactor has 4 vertical Mechanical Control Absorbers (MCAs), which are physically identical to the shutoff rods and reside outside the core during normal operation. They can be driven into the core for fast power decrease and can also be dropped into the core. MCAs are part of the Reactor Regulating System.

- Poison Injection Nozzles

A CANDU-6 core has six horizontal Liquid-poison (gadolinium nitrate solution) Injection Nozzles (LINS) located in the calandria vessel. Poison injection is part of SDS2. When SDS2 is triggered, a fast valve releases pressurized helium from a tank into the poison tanks, pushing poison into the unpressurized moderator.

⁹Rods made of materials characterized by modest neutron absorption are called “gray” rods. Rods made of materials characterized by strong neutron absorption are called “black” rods.

- Moderator Poison

Moderator poison (boron) is usually used to ensure guaranteed shutdown and is slowly removed during reactor startup to bring the reactor to criticality. It is also used when a reactor is first started up with a fresh core and until refueling equilibrium is reached. It is not used during normal operation after refueling equilibrium is reached. Moderator poison is part of the Reactor Regulating System.

A synopsis of reactivity devices is given in [Table 4](#) ([Rouben, 2002](#)) and a diagram of their location is shown in [Fig. 5](#).

It is important to note that all rods are perpendicular to the main axis of the cylindrical reactor core and that they reside or are inserted in guide tubes located between fuel channels in the unpressurized calandria vessel ([Fig. 6](#)) and thus cannot be accidentally ejected from the core.

Detectors

CANDU-6 reactors use a vast array of detectors for control and shutdown purposes, including proportional counters, ion chambers, and self-powered flux detectors (see [Han, 2021](#)). There are 174 active in-core detectors and 9 out-of-core detectors. Detectors are grouped into two separate groups depending on whether they are used for control or for shutdown. No detector belongs to both groups. Additionally, detectors for SDS1 and SDS2 are also separate. A list of detectors and their functions is given in [Table 5](#), adapted from ([Rouben, 2002](#)).

Reactor regulating system

CANDU-6 reactors have a fully digital control system. The Reactor Regulating System is a set of routines that run on a Digital Control Computer (DCC). There are two such DCCs, the first of which is active while the second one is in hot standby, able to take over seamlessly if the first one becomes unavailable. For power control purposes, the CANDU-6 core is divided into 14 power zones. Each zone has one ZCU and one detector assembly containing two (one active and one spare) fast self-powered platinum in-core detectors as shown in [Fig. 7](#). The power level in each zone is read by the respective detectors and is adjusted by lowering (for zone power increase) or raising (for zone power decrease) the water level in the respective ZCU.

Table 4 CANDU-6 reactivity devices ([Rouben, 2002](#)).

Function	Device	Total reactivity worth (pcm)	Maximum reactivity rate (pcm/s)
Control	14 Liquid Zone Controllers	700	± 14
Control	21 Adjuster Rods	1500	± 10
Control	4 Mechanical Control Absorbers	1000	± 7.5 (driving) -350 (dropping) - 1 (extracting)
Control	Moderator Poison		- 5000
Shutdown (Safety)	28 Shutoff Rods	8000	- 5000
Shutdown (Safety)	6 Liquid-Poison Injection Nozzles	> 30,000	- 5000

Fig. 7 Power zones and locations of ZCUs and zone detector assemblies in a CANDU-6 reactor (Front half of reactor, zones 1–7, shown. Back half of reactor consists of zones 8–14.)

The RRS routines serve the following functions:

- Maintaining core criticality between refuelings
 - o By slowly lowering the water level in all ZCUs, the core is maintained critical as fuel burns. When a channel is refueled the water level goes up in all ZCUs.
 - o If a fueling machine becomes unavailable, criticality is maintained by removing adjuster rods, one bank at a time.
- Bulk (total) power control
 - o Total power (captured by the sum of the 14 zone detector readings) is checked every 0.5 s and the water levels in all ZCUs are adjusted in the same direction if power deviates from its set value.
- Spatial power control
 - o Individual zone powers (captured by individual zone detector readings) are checked every 2 s and if a zone power deviates from its time-average target value, the water level in its ZCU is raised (to decrease zone power) or lowered (to increase zone power) as necessary.
- Dampening of Xenon oscillations¹⁰ using the 14 ZCUs
- Flux mapping
 - o Flux mapping is performed every 2 min using readings from 102 self-powered vanadium detectors.
- Startup maneuvers
- Rapid power reduction, if necessary, using the 4 MCAs

Shutdown systems

CANDU-6 reactors have two, completely separate, independent and physically different (using different physical principles) shutdown systems, labeled SDS1 and SDS2. Each of them is capable of independently shutting down the reactor. SDS1 consists of 28 “black” spring-loaded cadmium shutoff rods which drop into the core when SDS1 is triggered. Shutoff rods fall into the core through guide tubes located between fuel channels. Because the moderator is not pressurized, there is no ejection mechanism for these shutoff rods. SDS1 uses 34 in-core self-powered platinum detectors for high-power neutronic trips and has a total negative reactivity of 8000 pcm which can be inserted at a rate of 5000 pcm/s.

¹⁰¹³⁵Xe is a fission product and a strong neutron absorber. Its concentration increases in regions with high neutron flux and decreases in regions with low neutron flux. Because it is a strong neutron absorber, its accumulation leads to a flux decrease in the regions with originally high flux and its depletion leads to a flux increase in the regions with originally low flux. This phenomenon can lead to unwanted flux and power oscillations which need to be dampened.

SDS2 consists of six liquid-poison (gadolinium nitrate solution) horizontal injection nozzles which can inject up to 30,000 pcm negative reactivity at a rate of 5000 pcm/s. When SDS2 is triggered, liquid poison is pushed into the core by pressurized helium. Liquid injection will work even in a deformed-geometry core that may occur in a severe accident. SDS2 uses 24 in-core self-powered platinum detectors for high-power neutronic trips.

Emergency core cooling system

The Emergency Core Cooling System (ECCS) floods the core in case of a major break in the primary circuit. It injects (light) water into all headers so water reaches the core regardless of the location of the break. ECCS has three stages: a high-pressure stage which uses gas pressure to inject water into the core from a water tank outside the reactor building, a medium pressure stage which uses water from a dousing tank located at the top of the containment building, and a low-pressure stage which pumps water from the reactor building sump back into the reactor core via the emergency core cooling heat exchanger.

Containment system

For a single CANDU-6 reactor, the containment system consists of a plastic-lined concrete structure, a dousing system, air coolers, a filtered discharge system, and access air locks.

For very small breaks in the primary circuit, the air coolers are used to condense the steam released in the containment. For larger breaks, when pressure in the containment rises, the dousing system may be started either manually or automatically (on a pressure setpoint). The dousing system sprays light water from the dousing tank located at the top of the containment into the steam environment, thus lowering the temperature, which causes the steam to condense and, consequently, the pressure to drop. Dousing is automatically shut off when the pressure reaches a lower limit but is restarted if pressure increases again. This cycle can be repeated multiple times.

The containment system is designed to withstand the additional pressure caused by a large break in the primary circuit and its leak rate is designed to be smaller than 0.5% of the total volume per day. Any radioactivity release is expected to be reduced by a factor of 10,000 by the containment.

Variants of the CANDU system

The CANDU-6 is the most widely deployed CANDU system. CANDU-6 plants have been built and operated successfully in Canada (Point Lepreau and Gentilly-2), Argentina (Embalse), China (Qinshan phase II), Korea (Wolsong) and Romania (Cernavoda).

The CANDU-6 system is, however, only one example of a wider family of CANDU designs. In the early days of the CANDU program, each new build was seen as an opportunity to try different technical solutions and to improve the design. As a consequence, reactor and steam-supply system characteristics differ from site to site and from the CANDU-6 design. As an illustration, [Table 6](#), adapted from ([IAEA, 2002](#)), compares the characteristics of the CANDU-6 system with those of CANDU nuclear-power plants built at several locations in the Canadian province of Ontario, as well as at sites in India that also use CANDU-type technology.

Pressure-vessel heavy-water reactors

As the pressure-tube CANDU system was being developed and plants were built in Canada and internationally, a pressure-vessel system was being developed in Germany with a prototype being built in Germany and commercial plants being built in Argentina at the Atucha site.

The Atucha pressure-vessel HWRs use heavy water as both coolant and moderator. Although the two belong to different circuits, they are not physically separated, as the two circuits communicate. The fuel consists of 37-rod vertical fuel assemblies, each approximately 5-m tall. Fuel rods are arranged in a concentric-ring arrangement similar to the CANDU-6 one (1, 6, 12, 18). Fuel assemblies reside in vertical fuel-channel tubes approximately 11.5 cm in diameter. Fuel-channel tubes are arranged in a triangular pattern with a lattice pitch of 27.2 cm. The moderator is found outside the fuel-channel tubes and there is no calandria tube and no gas gap to provide thermal insulation between the fuel-channel tube and the moderator. The moderator is contained in a vertical cylinder-shaped moderator tank which is traversed axially by the fuel-channel tubes. The moderator tank resides inside the pressure vessel, with a lower plenum below it and an upper plenum above it. The top of the moderator tank communicates with the upper plenum through holes serving to nearly equalize the coolant and moderator pressures. The PHTS has two loops. The coolant enters the pressure vessel through the coolant inlets located near the top of the pressure vessel and flows downwards, outside the moderator tank, towards the lower plenum through a downcomer similar to the one in LWRs. The coolant then flows upwards through the fuel-channel tubes and through slits at the top of the fuel-channel tubes into the upper plenum and then out of the pressure vessel through the coolant outlets. The moderator enters the pressure vessel through moderator inlets and then through a ring-shaped inlet header located at the bottom of the tank and into the moderator tank. It leaves through an outlet ring-shaped header located at the top of the moderator tank and out of the pressure vessel through moderator outlet nozzles. As a special feature distinguishing the pressure-vessel HWRs from the LWRs, the upper and lower plena do not occupy the entire space between the cylindrical moderator tank and the approximately hemispherical top and bottom of the pressure vessel, but rather a small portion of it. In order to save on

Adapted from IAEA (2002) Technical Reports Series No. 407, 2002. *Heavy Water Reactors: Status and Projected Development*. International Atomic Energy Agency. Retrieved from: https://www-pub.iaea.org/MTCD/publications/PDF/TRS407_scr/D407_scr1.pdf.

Boric acid can be inserted into the system and then slowly removed to compensate for fuel burnup after the initial load. Finally, moderator temperature can be varied in order to achieve fine reactivity control in certain operating modes. The reactor can be shut down either by banks of black shutdown rods (SDS1) or by rapid injection of boric acid into the moderator (SDS2).

A generic diagram of the core is shown in Fig. 8, adapted from (IAEA, 2002). The Atucha 1 and 2 reactor systems differ in power and other technical specifications. Table 7, adapted from (IAEA, 2002), shows the main parameters of the two systems.

Prototypes, advanced designs, and advanced-fuel-cycles

Prototypes

In addition to the large heavy-water power reactors in current commercial operation, a number of prototype heavy-water power reactors have been designed, built and operated over time. These were usually lower-power reactors (<200 MWe), oftentimes operated only for a few years, primarily as proofs of concept, to demonstrate the feasibility of specific technical solutions. Table 8, adapted from (IAEA, 2002), summarizes the characteristics of early prototype reactors. Interested readers can find additional details in (IAEA, 2002).

As Table 8 illustrates, prototype reactors have utilized a wider array of technical options (e.g., gas and boiling-light-water coolant) than the heavy-water systems in current commercial operation.

Advanced designs

In recent years, advanced CANDU designs have also been developed, most notably the Advanced CANDU Reactor (ACR). The ACR retains the horizontal pressure-tube design but has a tighter lattice pitch, of only 24 cm, and is cooled by pressurized light, rather than heavy, water. The fuel bundles have 43 fuel elements, instead of the 37 fuel elements used by the CANDU-6 design and fuel pellets consist of slightly enriched (<2.5%) UO_2 . The ACR retains both the shutoff-rod and liquid-poison-injection shutdown systems but the light-water zone control units are replaced by control blades. Finally, a supercritical-water-cooled pressure-tube heavy-water-moderated reactor is part of the Generation-IV International Forum whereby a preliminary design is still being developed.

Advanced fuel cycles

Because of their excellent neutron economy, fuel-channel design and on-line refueling, CANDU reactors can accommodate other fuel cycles besides natural uranium, such as low-enriched (usually <1.2%) uranium, recycled uranium (from LWR) and thorium (Foster and Critoph, 1975). Because of their good neutron economy, CANDU reactors can allow the direct use of used PWR fuel (including fission products), a technology known as Direct Use of PWR Fuel in CANDU (DUPIC, Park et al., 2008).

CANDU cores can also use thorium-based fuel cycles. ^{232}Th is a fertile nuclide which, under neutron irradiation, is converted to the fissile nuclide ^{233}U . To initiate fission, some fissile material (driver) needs to be initially present in the core. Driver fuel can come in the form of natural uranium, recycled uranium or DUPIC fuel (Jeong et al., 2008). Used fuel can either be disposed of, in the case of a once-through fuel cycle, or processed to extract ^{233}U to be used, alongside ^{232}Th , to fuel the reactor, in the case of a closed fuel cycle. Theoretically, over time, all fissile material fueling the reactor (alongside ^{232}Th) could be in the form of ^{233}U recovered from used fuel. In practice, the amount of ^{233}U that can be extracted from used fuel is less than the amount of fissile material needed to refuel the reactor to maintain criticality. Consequently, even in the case of a closed Th fuel cycle, some fissile material besides ^{233}U needs to be used in the core (either mixed with recycled ^{233}U or separate). The additional fissile material can be in the form of natural uranium, recycled uranium, or DUPIC fuel (Jeong et al., 2008; St-Aubin and Marleau, 2015).

 WNA World Nuclear Association

The number of operating commercial nuclear power reactors in each country is something that changes on a regular basis as new units come into service and others are permanently shut down. As a result, the information presented in this section is a snapshot for each country as of January 2021.

More up-to-date information can be obtained by accessing the IAEA Power Reactor Information System (PRIS) database or the World Nuclear Association (WNA) country profile pages using the links provided in the Relevant Webpages section. The American Nuclear Society (ANS) also publishes a list of operable, under construction, or on order nuclear reactors once per year in its Nuclear News magazine. ANS also publish a booklet with this information and maps that show the locations of the reactors in each country.

Global statistics

Fig. 1 presents total world-wide nuclear electricity production from 1970 to 2019, with color coding to show how much was produced in each of six regions. Total production for 2019 was 2657 TWh.

Fig. 2 shows the nuclear generation capacity in GWe for reactors that were classified as operable from 1970 through 2019. The top of the blue bar for each year is the actual amount of nuclear generation that occurred from operable reactors.

Fig. 3 presents the global average capacity factor for reactors that generated electricity during the period from 1970 to 2019. The global average capacity factor was 82.5% in 2019.

Fig. 4 presents the capacity factor by reactor type for the years 2014 through 2018, as well as for 2019. Five of the six reactor types had better performance in 2019 than their average performance for 2014–18.

Fig. 1 Nuclear electricity production by region. World Nuclear Association, World Nuclear Performance Report 2020, Report 2020/008, August 2020, Figure 1.

Fig. 2 Nuclear generation capacity for operable reactors. World Nuclear Association, World Nuclear Performance Report 2020, Report 2020/008, August 2020, Figure 2.

Fig. 3 Global average capacity factor. World Nuclear Association, World Nuclear Performance Report 2020, Report 2020/008, August 2020, Figure 4.

Fig. 4 Capacity factor by reactor type. World Nuclear Association, World Nuclear Performance Report 2020, Report 2020/008, August 2020, Figure 5.

Fig. 5 Long-term trends in capacity factor. World Nuclear Association, World Nuclear Performance Report 2020, Report 2020/008, August 2020, Figure 9.

Fig. 6 Reactors first grid connection and shutdown, 1954–2019. World Nuclear Association, World Nuclear Performance Report 2020, Report 2020/008, August 2020, Figure 13.

Fig. 5 shows the percentage of operating reactors that obtained specific ranges of capacity factors. Capacity factors improved substantially from the 1970s through to the 2000s. Since then, this high performance has been maintained.

Fig. 6 shows the number of reactors that first connected to the grid and the number that were permanently shut down from 1954 through 2019. The majority of the reactors that permanently shut down in 2019 actually ceased generation between 2011 and 2017.

The above figures and additional information about them can be found in the World Nuclear Performance Report 2020, which is published by the World Nuclear Association. New versions of this report are issued on a yearly basis.

Country statistics

Table 1 summarizes the number of reactors in operation and under construction and their associated net electrical capacity in each country. Approximate capacity factor values for 2018 are also presented in Table 1 for each country with operating reactors.

The subsections which follow for each country provide details on the type of reactors that are found in each country.

Table 1 Reactors in operation, under construction and shut down by country.

Country	In operation		Under construction		Shut down	
	Number	Electrical net output (MW)	Number	Electrical net output (MW)	Number	2018 Production (GWh) Approx. capacity factor (%)

Approximate capacity factor has been calculated based on total nuclear production for 2018 divided by the theoretical maximum generation if all operating plants in the country were to run at full rated electrical net output for the entire year. For Japan, it was calculated based on the capacity of the nine operating units instead of the entire fleet of 37 units that remain operational.

Source: IAEA PRIS database summary, January 2021.

Argentina

Argentina's first nuclear reactor was designed by Siemens and began operation in 1974. In 2018 with one of its reactors down for a lifetime extension program, nuclear power accounted for 5% of Argentina's electricity production.

Argentina has three operating pressurized heavy water reactor (PHWR) units with a combined net electrical capacity of 1641 MW. One pressurized water reactor (PWR) unit with a planned net electrical capacity of 25 MW is under construction.

Armenia

Armenia's nuclear reactors were an early Soviet VVER design, the first of which began operating in 1976. In 2018, nuclear power accounted for 27% of Armenia's electricity production.

Armenia has one operating PWR unit with a net electrical capacity of 375 MW. Armenia also has one reactor that has been permanently shut down.

Bangladesh

Bangladesh started construction of its first nuclear power reactor in November 2017. The unit is scheduled to be commissioned in 2023.

Bangladesh has two PWR units under construction with a planned combined net electrical capacity of 2160 MW. Atomstroyexport is building the two VVER-1200 reactors.

Belarus

Belarus connected its first nuclear power reactor to the grid in November 2020.

Belarus has one operating PWR unit with a net electrical capacity of 1110 MW, and one PWR unit under construction with a planned combined net electrical capacity of 1110 MW. Atomstroyexport is building the two VVER-1200 reactors.

Belgium

Belgium's first commercial nuclear reactor began operating in 1974. In 2018, nuclear power accounted for 38% of Belgian electricity production.

Belgium has seven operating PWR units with a combined net electrical capacity of 5942 MW. Belgium also has one reactor that has been permanently shut down. Westinghouse and Framatome have both designed PWRs in Belgium.

Brazil

Brazil's first commercial nuclear reactor was designed by Westinghouse and began operating in 1982. In 2018, nuclear power accounted for 3% of Brazilian electricity production.

Brazil has two operating PWR units with a combined net electrical capacity of 1884 MW. One PWR unit is under construction with a planned net electrical capacity of 1340 MW. Kraftwerk Union (KWU) designed the second and third Brazilian PWR units.

Bulgaria

Bulgaria's commercial nuclear reactors were designed by the Soviets and the first unit began operating in 1974. In 2018, nuclear power accounted for 34% of Bulgarian electricity production.

Bulgaria has two operating PWR units with a combined net electrical capacity of 2006 MW. Bulgaria also has four reactors that were permanently shut down as a result of Bulgaria's agreement to join the European Union in January 2007.

Canada

In 2018, nuclear power accounted for 15% of Canadian electricity production.

Canada has 19 operating PHWR units designed by Atomic Energy of Canada, Ltd. (AECL) with a combined net electrical capacity of 13,554 MW. Canada also has six reactors that have been permanently shut down.

China

The first nuclear power plant in China was a PWR provided by Mitsubishi Heavy Industries of Japan. Westinghouse, Areva/Framatome, Atomstroyexport (Russia) and Atomic Energy of Canada, Ltd. have also supplied PWRs and PHWRs to China, but most Chinese plants are now of Chinese design. In 2018, nuclear power accounted for 4% of Chinese electricity production.

China has 47 operating PWR units, two operating PHWR units and one liquid metal fast breeder reactor (LMFBR) unit with a combined net electrical capacity of 47,518 MW. Eleven PWR units with a combined net electrical capacity of 8200 MW are under construction. One gas cooled reactor (GCR) unit, one liquid metal fast breeder reactor (LMFBR) units and about 20 PWR units are planned but not yet under construction.

Czech Republic

The Czech Republic's commercial nuclear power reactors were designed by the Soviets and the first unit began operating in 1985. In 2018, nuclear power accounted for 34% of electricity production in the Czech Republic.

The Czech Republic has six operating PWR units with a combined net electrical capacity of 3932 MW.

Finland

In 2018, nuclear power accounted for 32% of Finnish electricity production.

Finland has two operating boiling water reactor (BWR) units and two operating PWR units with a combined net electrical capacity of 2784 MW. One PWR unit with a planned net electrical capacity of 1600 MW is under construction. One additional PWR with a planned net electrical capacity of 1200 MW is planned but has not started construction. The operating BWRs were designed by ASEA Atom and the operating PWRs were designed by the Soviets. The PWR that is under construction was designed by Areva and is currently expected to begin operating in 2021.

France

In 2017, nuclear power accounted for 71% of French electricity production.

France has 56 operating PWR units with a combined net electrical capacity of 61,360 MW. One PWR unit with a planned net electrical capacity of 1600 MW is under construction. France has 14 reactors that have been permanently shut down. All French reactors were designed by Framatome or its successor, Areva.

Germany

In 2018, nuclear power accounted for 12% of German electricity production. General Electric designed the first BWR in Germany, which is now shut down. All operating German reactors were designed by Siemens-KWU. Several Soviet-designed reactors existed in East Germany at the time of German reunification, but all of them were shut down due to safety concerns.

Germany has one operating BWR unit and five operating PWR units with a combined net electrical capacity of 8113 MW. Germany has 30 reactors that have been permanently shut down.

Hungary

Hungary's commercial nuclear power reactors were designed by the Soviets and the first unit began operating in 1982. In 2018, nuclear power accounted for 49% of Hungarian electricity production.

Hungary has four operating PWR units with a combined net electrical capacity of 1902 MW.

India

General Electric designed India's two BWRs, which began operation in 1969. AECL designed the first two PHWRs in India. Subsequent PHWRs were designed locally in India. More recently, Atomstroyexport started providing PWRs to India. In 2018, nuclear power accounted for 2.4% of Indian electricity production.

India has two operating BWR units, 19 operating PHWR units and two operating PWR units with a combined net electrical capacity of 6885 MW. One LMFBR unit, three PHWR units and two PWR units with planned combined net electrical capacities of 4194 MW are under construction. Additional PHWR units and PWR units are planned but not yet under construction.

Iran

In 2018, nuclear power accounted for 2% of Iranian electricity production.

Iran has one operating PWR unit with a net electrical capacity of 915 MW. One additional PWR unit with a net electrical capacity of 974 MW is under construction. The operating PWR started construction in 1975, but did not connect to the grid until 2011. The original design was from Siemens-KWU, but construction was abandoned after the Iranian revolution. The plant was eventually completed with help from the Russians.

Italy

Italy has had four operating nuclear power reactors but the last two were permanently shut down following the Chernobyl accident.

Japan

In 2017, nuclear power accounted for 3% of Japanese electricity production.

The first Japanese BWRs of BWR/2 through BWR/5 product lines were designed by General Electric. Subsequent BWRs of these product lines were built by Hitachi or Toshiba under license from General Electric. The Kashiwazaki Kariwa ABWR units were designed jointly by General Electric, Hitachi and Toshiba.

The first Japanese PWR was designed by Westinghouse. Subsequent Japanese PWRs were designed by Mitsubishi Heavy Industries under license from Westinghouse.

Prior to the Great East Japan Earthquake of March 11, 2011, and the subsequent disaster at the Fukushima Daiichi Nuclear Power Plant, there were 54 operating nuclear reactors in Japan.

As of the writing of this chapter, Japan has 17 BWR units with a combined net electrical capacity of 17,559 MW that remain operational, but none of them are currently in operation. Japan also has 16 PWR units with a combined net electrical capacity

of 14,120 MW that remain operational. Nine of these PWRs with a combined net electrical capacity of 8706 MW are currently in operation. Two BWR units with a combined net electrical capacity of 2653 MW are under construction. Japan has 27 reactors that are permanently shut down.

Kazakhstan

Kazakhstan operated a single Russian nuclear power LMFBR from 1972 to 1999, generating electricity and desalinating water. It is now permanently shut down.

Lithuania

Lithuania has had two operating Russian light water cooled graphite moderated reactors (LGRs). However, due to strong European Union (EU) concerns about the LGR design, by the time Lithuania applied to join the EU it was required to close them both down.

Mexico

Mexico's commercial nuclear reactors were designed by General Electric, and the first one began operating in 1989. In 2018, nuclear power accounted for 4% of Mexican electricity production. Mexico has two operating BWR units with a combined net electrical capacity of 1552 MW.

Netherlands

In 2018, nuclear power accounted for 3% of electricity production in The Netherlands.

The Netherlands has one operating PWR unit designed by Siemens-KWU with a net electrical capacity of 482 MW. The Netherlands also had a smaller General Electric natural circulation BWR unit that operated from 1968 until it was permanently shut down in 1997.

Pakistan

In 2018, nuclear power accounted for 7% of electricity production in Pakistan.

Pakistan has four operating PWR units and one operating PHWR unit with a combined net electrical capacity of 1318 MW. Two PWR units with a combined net electrical capacity of 2028 MW are under construction. One additional PWR unit with a net electrical capacity of 1000 MW is planned but not yet under construction. Pakistan's PWR units were designed by the Chinese. AECL designed the PHWR unit.

Romania

In 2018, nuclear power accounted for 18% of Romanian electricity production.

Romania has two operating PHWR units with a combined net electrical capacity of 1300 MW. Two PHWR units with a combined net electrical capacity of 1440 MW are planned but are not yet under construction. AECL designed the Romanian PHWRs units.

Russia

In 2018, nuclear power accounted for 18% of Russian electricity production.

Russian companies have designed all of Russia's reactors and are a major exporter of nuclear reactor technology. Russia has 12 operating light water-cooled graphite reactor (LGR) units, two operating LMFBR units and 24 operating PWR units with a combined net electrical capacity of 28,578 MW. Three PWR units with a combined net electrical capacity of 3459 MW are under construction. Russia has nine reactors that are permanently shut down.

Slovakia

In 2018, nuclear power accounted for 53% of Slovakian electricity production.

Slovakia has four operating PWR units with a combined net electrical capacity of 1814 MW. Two additional PWR units with a combined net electrical capacity of 880 MW are under construction. Slovakia also has three reactors that are permanently shut down. Two of them were shut down as a precondition for Slovakia's entry into the European Union in 2004.

Slovenia

Slovenia has shared ownership of its one reactor with Croatia since 1981. In 2018, nuclear power accounted for 39% of electricity production in Slovenia.

Slovenia has one operating Westinghouse PWR unit with a net electrical capacity of 688 MW.

South Africa

South Africa's commercial nuclear power reactors were designed by Framatome (now Areva) and the first one began operating in 1984. In 2018, nuclear power accounted for 5% of South African electricity production.

South Africa has two operating PWR units with a net electrical capacity of 1860 MW.

South Korea

In 2018, nuclear power accounted for 23% of South Korean electricity production.

The early PWRs in South Korea were designed by Westinghouse, Combustion Engineering and Framatome. Subsequent PWRs based on the Combustion Engineering design have been built by South Korean suppliers. South Korea has three operating PHWR units and 21 operating PWR units with a combined net electrical capacity of 23,172 MW. Four additional PWR units with a combined net electrical capacity of 5360 MW are under construction. South Korea has two reactors that are permanently shut down.

Spain

In 2018, nuclear power accounted for 20% of Spanish electricity production.

BWRs in Spain were designed by General Electric. Kraftwerk Union AG (KWU) designed one PWR with the remaining PWRs being designed by Westinghouse. Spain has one operating BWR unit and six operating PWR units with a combined net electrical capacity of 7121 MW. Spain has three reactors that are permanently shut down.

Sweden

In 2018, nuclear power accounted for 42% of Swedish electricity production. BWRs in Sweden were designed by ASEA Atom, which is today part of Westinghouse. Swedish PWRs were designed by Westinghouse. Sweden has four operating BWR units and two operating PWR units with a combined net electrical capacity of 6859 MW. Sweden has seven reactors that are permanently shut down.

Switzerland

In 2017, nuclear power accounted for 32% of Swiss electricity production. General Electric Technical Services Company (the international division of General Electric) designed two Swiss BWR plants. Westinghouse and KWU designed Swiss PWR units. Switzerland has one operating BWR unit and three operating PWR units with a combined net electrical capacity of 2960 MW. Switzerland has two reactors that are permanently shut down.

Taiwan

In 2017, nuclear power accounted for 8% of electricity production in Taiwan. General Electric designed all BWRs in Taiwan, while Westinghouse designed all PWRs. Taiwan has two operating BWR units and two operating PWR units with a combined net electrical capacity of 3844 MW. Two additional BWRs are under construction at the Lungmen site with a combined net electrical capacity of 2600 MW, but construction has been suspended. Taiwan has two reactors that are permanently closed.

Turkey

Turkey is constructing its first nuclear power plants, which are designed by Atomstroyexport of Russia. Turkey has two PWR units under construction with a planned net electrical capacity of 2228 MW. Two additional PWR units with a combined net electrical capacity of 2228 MW are planned but have not started construction.

Ukraine

In 2017, nuclear power accounted for 55% of electricity production in Ukraine. Ukraine's nuclear plants were all designed by a Russian supplier. Ukraine has 15 operating PWR units with a combined net electrical capacity of 13,107 MW. Two additional PWR units with a combined net electrical capacity of 2070 MW are under construction. Ukraine has four reactors that are permanently closed.

United Arab Emirates

The United Arab Emirates is constructing its first nuclear power plants, which are designed by South Korea. The first of four units was connected to the grid in August 2020. The United Arab Emirates has one operating PWR with a net electrical capacity of 1345 MW. Three additional PWR units with a combined net electrical capability of 4035 MW are under construction.

Table 2 Annual capacity factors for nuclear generation in the United States.

Period	Annual capacity factors for nuclear generation
2013	89.9%
2014	91.7%
2015	92.3%
2016	92.3%
2017	92.2%
2018	92.6%

U.S. Energy Information Administration (2019) *Electric Power Monthly, Data for July 2019, Table 6.7.B. Capacity Factors or Utility Scale Generators Not Primarily Using Fossil Fuels, January–July 2019*. Available from https://www.eia.gov/electricity/monthly/epm_table_grapher.php?t=epmt_6_07_b

United Kingdom

In 2018, nuclear power accounted for 20% of electricity production in the United Kingdom. Operating plants were designed by companies in the United Kingdom. Areva designed the PWRs that are under construction.

The United Kingdom has 14 gas-cooled reactor (GCR) units and one PWR unit with a combined net electrical capacity of 8923 MW. Two additional PWRs with a combined net electrical capacity of 3260 MW are under construction. The United Kingdom has 30 reactors that are permanently shut down.

United States

In 2018, nuclear power accounted for 19% of electricity production in the United States. The United States has 31 operating BWR units and 63 operating PWR units with a combined net electrical capacity of 96,553 MW. Two PWR units with a combined net electrical capacity of 2234 MW are under construction. The United States has 39 reactors that are permanently shut down.

The annual capacity factors for nuclear power generation in the United States for 2013 through 2018 are provided in **Table 2**.

Introduction: Electricity generation in the world and selected countries

It is well-known that electricity generation and its consumption are the key factors for advances in industry, agriculture, technology, and the level of living. **Table 1** shows clearly a strong dependence of Human Development Index (HDI) (Rows No. 4 and 5) from Electrical-Energy Consumption (EEC) per capita (Row 3); current population is shown in Row 1 (for details, see [Pioro et al. \(2019, 2020\)](#); [Pioro \(2016\)](#); [Pioro and Duffey \(2015\)](#)). Also, robust power industry with diverse energy sources is very important for a country's economic and political independence.

In general, electricity (see **Table 1**) can be generated from: (1) traditional fuels (i.e., non-renewable sources) such as coal, natural gas, oil, and nuclear utilizing mined resources; and (2) so-called, "renewables" such as hydro, biomass, wind, geothermal, solar, and marine (tidal and wave) power utilizing geotechnical resources.

Today, the main sources for global electrical-energy generation (see **Table 1**) are: (1) Thermal power—primarily using coal (38.3%) and secondarily using natural gas (22.9%); (2) "Large" hydro-electric power plants (16.3%); and (3) Nuclear power (10.2%). The rest 12.3% of the electrical energy is generated using renewables (wind, biomass, geothermal, solar, and marine energy) (6.6%), oil (3.3%), and other sources (2.4%).

Table 1 also lists 13 countries, which have the largest number of nuclear-power reactors/their installed capacities. These countries are listed according to the decreasing population.

Analysis of the data in **Table 1** shows that the world (~38%) and, especially, countries with the largest population, i.e., China (~66%) and India (~75%), as well as Germany (~37%) and South Korea (~42%) rely heavily on coal for the electricity generation. The United States (~39%), Russia (~59%), Japan (~37%), and United Kingdom (~44%) use mainly natural gas or

Table 1 Electricity generation in the world and selected countries by source (data on the world and 13 countries with largest installed capacities of nuclear-power reactors are located by decreasing population).

Population is taken from <https://www.worldometers.info/world-population/population-by-country/> (data for January 2021); EEC from https://en.wikipedia.org/wiki/List_of_countries_by_Human_Development_Index (data are from 2017; for exact details see the reference); and HDI from https://en.wikipedia.org/wiki/List_of_countries_by_Human_Development_Index and http://hdr.undp.org/sites/default/files/2018_human_development_statistical_update.pdf (data from 2018—Report of 2019); and data on electricity-generating sources from 2018 (<https://www.statista.com/>). (More diagrams for other countries and/or for previous years are shown in [Pioro et al. \(2019, 2020\)](#); [Pioro \(2016\)](#); [Pioro and Duffey \(2015\)](#)).

^a $EEC/\frac{W}{Capita} = \left(\frac{EEC, \frac{GW \cdot h}{year}}{(Population, Millions) \times 10^6} \right) \times \frac{10^9}{365 \text{ days} \times 24 \text{ h}}$; Electrical Energy Consumption (EEC) compares the total electricity generated annually plus imports and minus exports, expressed in GigaWatt-hours (GW · h).

^bHDI: Human Development Index by United Nations (UN); HDI is a comparative measure of life expectancy, literacy, education, and standards of living for countries worldwide. HDI is calculated with the following formula: $HDI = \sqrt[3]{LEI \times EI \times II}$, where LEI, life expectancy index; EI, education index; II, income index. It is used to distinguish whether the country is a developed, a developing or an underdeveloped, and also to measure the impact of economic policies on quality of life.

Fig. 1 Aerial view of the largest operating NPP in the world—6288-MW_{el} Bruce NPP (courtesy of Bruce NPP: www.brucepowers.com). (The Douglas Point NPP (see left upper corner) was Canada's first full-scale NPP and the second CANDU reactor. Its success was a major milestone for Canada to enter the global nuclear-power scene. Construction began on Feb. 1, 1960 and decommission date: May 4, 1984).

Liquefied Natural Gas (LNG) for electricity generation, which is better than to use coal, but still, for now, we cannot avoid emissions of carbon dioxide and NO_x due to a combustion process. On opposite, France (~72%) and Ukraine (~54%) rely heavily on nuclear power, which is, in general, the lowest emitter of carbon dioxide compared to all other electricity-generating sources including renewables (for details, see [Pioro et al., 2019](#)). Canada and Sweden are the only countries from the 13 ones, which rely heavily on the hydro electricity generation ~61% and ~39%, respectively.

Analysis of the data on installed capacities of various power plants in the world (https://en.wikipedia.org/wiki/List_of_largest_power_stations) shows that the 22 largest power plants have installed capacities ranging within 5700–22,500 MW_{el}. Within these power plants the largest group is hydro plants (in total 12) with installed capacities ranging from 5850 and up to 22,500 MW_{el}, six Nuclear Power Plants (NPPs) (installed capacities 5700–7965 MW_{el}) (for now, the largest in the world NPP—Kashiwazaki-Kariwa NPP is not in service after the Fukushima-Daiichi NPP severe accident in March of 2011), 2 coal- and 1 gas-fired thermal power plants (installed capacities 6040–8695 MW_{el}), and 1 wind power plant (installed capacity 7965 MW_{el}). **Fig. 1** shows aerial view of the largest operating NPP in the world—6288-MW_{el} Bruce NPP (Province of Ontario, Canada).

Basic general parameters of power plants

Thermal efficiency

In general, efficiency (thermal efficiency) is one of the most important parameters of any power plant ([Pioro et al., 2019, 2020; Pioro, 2016](#)):

Gross (overall) efficiency (for details, see [Table 2](#)) during a given period of time is the ratio of the gross electrical energy generated by a unit to the energy consumed during the same period by the same unit. The difference between gross and net efficiencies is the internal usage of a power plant, which might be not so small (5% or even more). Also, the thermal efficiency is the driving force for advances in thermal power plants and, nowadays, in NPPs.

Analysis of the data listed in [Table 2](#) shows that the top power plants by the thermal efficiency are: (1) Combined-cycle power plants (combination of Brayton gas-turbine cycle and subcritical-pressure Rankine steam-turbine cycle) (for details, see Appendix A1 in [Pioro, 2016](#)) with the highest thermal efficiency in the power industry of up to 62%, which means that roughly 2/3 of thermal energy introduced inside the combined power cycle is used for electricity generation, i.e., useful energy (in general, “useful” energy can include electricity; process heat; hot water/steam for heating of buildings, hot-water supply, etc.; and desalination) and only 1/3 of the total energy is lost into environment; and (2) Supercritical-pressure Rankine steam-turbine cycle of coal-fired power plants with up to 55% thermal efficiency (for details, see Appendix A1 in [Pioro \(2016\)](#) and [Pioro and Duffey \(2007\)](#)). Unfortunately, NPPs

Table 2 Typical ranges of thermal efficiencies (gross) of modern thermal and nuclear power plants (Pioro et al., 2019, 2020; Pioro, 2016).

No	Power plant	Gross thermal efficiency
1	Combined-cycle power plant combination of Brayton gas-turbine cycle (fuel—natural gas or LNG; combustion-products parameters at gas-turbine inlet: $P_{in} \approx 2.5$ MPa, $T_{in} \approx 1650$ °C) and Rankine steam-turbine cycle (steam parameters at turbine inlet: $P_{in} \approx 12.5$ MPa ($T_{sat} = 327.8$ °C), $T_{in} \approx 620$ °C ($T_{cr} = 374$ °C)). (For details, see Fig. 2)	Up to 62%
2	Supercritical-pressure coal-fired power plant (Rankine-cycle steam inlet turbine parameters: $P_{in} \approx 23.5$ –38 MPa ($P_{cr} = 22.064$ MPa), $T_{in} \approx 540$ –625 °C ($T_{cr} = 374$ °C); and $P_{reheat} \approx 4$ –6 MPa ($T_{sat} = 250.4$ –275.6 °C), $T_{reheat} \approx 540$ –625 °C). (For details, see Fig. 3)	Up to 55%
3	Internal-combustion-engine generators (Diesel cycle and Otto cycle with natural gas as fuel)	Up to 50%
4	Subcritical-pressure coal-fired power plant (older plants; Rankine-cycle steam: $P_{in} = 17$ MPa ($T_{sat} = 352.3$ °C), $T_{in} = 540$ °C ($T_{cr} = 374$ °C); and $P_{reheat} \approx 3$ –5 MPa ($T_{sat} = 233.9$ –263.9 °C), $T_{reheat} = 540$ °C). (For T -s diagram, see Fig. 5C)	Up to 43%
5	Carbon-dioxide-cooled reactor (Advanced Gas-cooled Reactor (AGR)) NPP (Generation-III) (reactor coolant: $P = 4$ MPa, $T = 290$ –650 °C; and steam: $P_{in} = 17$ MPa ($T_{sat} = 352.3$ °C) and $T_{in} = 560$ °C ($T_{cr} = 374$ °C); and $P_{reheat} \approx 4$ MPa ($T_{sat} = 250.4$ °C), $T_{reheat} = 560$ °C). (For schematic and layout, see Fig. 4A and B, and for T -s diagram—Fig. 5C)	Up to 42%
6	Sodium-cooled Fast Reactor (SFR) (BN-600 & BN-800) NPP (steam: $P_{in} = 14.2$ MPa ($T_{sat} = 337.8$ °C), $T_{in} = 505$ °C ($T_{cr} = 374$ °C); and $P_{reheat} \approx 2.5$ MPa ($T_{sat} = 224$ °C), $T_{reheat} = 505$ °C). (For details, see Fig. 5A–C)	Up to 40%
7	Pressurized-Water-Reactor (PWR) NPP (Generation-III ⁺) (reactor coolant: $P = 15.5$ MPa ($T_{sat} = 344.8$ °C), $T_{out} = 327$ °C; steam: $P_{in} = 7.8$ MPa, $T_{in} = T_{sat} = 293.3$ °C; and $P_{reheat} \approx 2$ MPa ($T_{sat} = 212.4$ °C), $T_{reheat} \approx 265$ °C). (For details, see Fig. 6A–C)	Up to 36–38%
8	Pressurized-Water-Reactor (PWR) NPP (Generation-III, current fleet) (reactor coolant: $P = 15.5$ MPa ($T_{sat} = 344.8$ °C), $T = 292$ –329 °C; steam: $P_{in} = 6.9$ MPa, $T_{in} = T_{sat} = 284.9$ °C; and $P_{reheat} \approx 1.5$ MPa ($T_{sat} = 198.3$ °C), $T_{reheat} \approx 255$ °C). (For details, see Fig. 6, and for T -s diagram—Fig. 6C)	Up to 34–36%
9	Boiling-Water-Reactor (BWR) NPP (Generation-III, current fleet) reactor coolant: $P = 7.2$ MPa, $T_{out} = T_{sat} = 287.7$ °C; steam: $P = 7.2$ MPa, $T_{in} = T_{sat} = 287.7$ °C and $P_{reheat} \approx 1.7$ MPa ($T_{sat} = 204.3$ °C), $T_{reheat} \approx 258$ °C. (For schematic and layout, see Fig. 7A and B, and for T -s diagram—Fig. 6C)	Up to 34%
10	Light-water-cooled Graphite-moderated Reactor (LGR) (Russian RBMK-1000) NPP (Generation-III, current fleet) (reactor coolant: $P = 6.4$ MPa, $T_{out} = T_{sat} = 279.8$ °C; steam: $P = 6.4$ MPa, $T_{in} = T_{sat} = 279.8$ °C and $P_{reheat} \approx 0.3$ MPa ($T_{sat} = 133.5$ °C), $T_{reheat} \approx 263$ °C). (For schematic and layout, see Fig. 8A and B and for T -s diagram—Fig. 6C)	Up to 34%
11	Pressurized Heavy Water Reactor (PHWR) NPP (Generation-III, CANDU [®] -6, current fleet) reactor coolant: $P_{in} = 11$ MPa/ $P_{out} = 9.9$ MPa ($T_{sat} = 310.3$ °C) and $T = 260$ –310 °C; steam: $P_{in} = 4.7$ MPa, $T_{in} = T_{sat} = 260.1$ °C; and $P_{reheat} \approx 1.2$ MPa ($T_{sat} = 188$ °C), $T_{reheat} \approx 240$ °C. (For schematic and layout, see Figs. 9A and B and for T -s diagram—Fig. 6C)	Up to 32% (34%)
12	PWR SMR NPP (RITM-200M, Russia) (Generation-III ⁺) (not yet in operation as SMR NPP ^a) reactor coolant: $P = 15.7$ MPa ($T_{sat} = 345.8$ °C), $T = 277$ –313 °C; steam: $P_{in} = 3.82$ MPa, $T_{in} = 295$ °C ($T_{sat} = 247.6$ °C). (For layout, see Fig. 10B and for T -s diagram—Fig. 10D)	Up to ~31%
13	PWR SMR NPP (KLT-40S, Russia) (Generation-III, current fleet) reactor coolant: $P = 12.7$ MPa ($T_{sat} = 329$ °C), $T = 280$ –316 °C; steam: $P_{in} = 3.72$ MPa, $T_{in} = 290$ °C ($T_{sat} = 246.1$ °C). (For details, see Fig. 10A, C and D)	Up to ~26%

^aIn 2021, Rosatom will begin work on a site of the future SMR NPP, which is planned to be built in Yakutia. The SMR will be a RITM-200 ship-based reactor (<https://www.neimagazine.com/news/newsrosatom-to-being-work-on-land-based-smr-8436408>).

with subcritical-pressure Rankine steam-turbine cycle have significantly lower thermal efficiencies up to 1.5–2.4 times compared to those of the top thermal power plants.

It is reasonable to compare NPPs with various types of nuclear-power reactors based on thermal efficiencies (for details, see Table 2 and Figs. 3C, 6C and 8C), where AGR NPPs have the highest thermal efficiency in the nuclear-power industry of up to 42% (Figs. 2 and 3C), and SFR NPPs—up to 40% (Fig. 3). Such relatively high thermal efficiencies are due to higher temperatures inside reactors (in AGRs the outlet temperature of the carbon-dioxide reactor coolant is up to 650 °C, and in SFRs with the liquid-sodium reactor coolant—up to 550 °C), adopting subcritical-pressure Rankine cycles with primary and secondary superheated steam and relatively high primary-steam pressures—17 MPa and 14.2 MPa, respectively.

However, the last AGR (only 14 left in United Kingdom) was connected to a grid in 1989, i.e., with no new AGRs have been built for last 32 years. Possible reasons for stopping AGRs in the United Kingdom were the cost, build difficulties (problems with intermediate heat exchangers and thermal insulation), and issues with attaining on-line refueling at full-power plus lower costs alternatives. Therefore, unfortunately, these reactors/NPPs will be never built again.

In terms of SFRs, only two are currently in operation in Russia, and the relatively low boiling point of sodium (882.8 °C) means that these unique fast reactors/NPPs will not possibly have higher thermal efficiencies in the future. Currently, China is finalizing

Fig. 2 Simplified layout (A) and T - s diagram (saturation line is only related to Rankine cycle) (B) of modern combined-cycle power plant (based on data from MHI and Siemens) (Pioro, 2016).

Fig. 3 (A) Single-reheat regenerative cycle 600-MW_{el} Tom'-Usinsk thermal power plant (Russia) layout (Kruglikov et al., 2009): Cyl—Cylinder; H—Heat exchanger (feedwater heater); CP—Circulation Pump; TDr—Turbine Drive; Cond P—Condensate Pump; GCHP—Gas Cooler of High Pressure; and GCLP—Gas Cooler of Low Pressure. (B) Simplified *T-s* diagram of supercritical-pressure Rankine steam-turbine cycle. Shown Rankine cycle is typical one for next generation or Generation-IV SuperCritical Water-cooled Reactors (SCWRs) (for exact parameters of SCWRs, see Table 3) and can be used in Lead-cooled Fast Reactor (LFR) NPP (at least, for Russian BREST-300 reactor).

Fig. 3 (continued).

construction of the first China Fast Reactor (CFR-600) and has started construction of another one (<https://www.neimagazine.com/news/newschina-begins-construction-of-second-cfr-600-fast-reactor-8435608>).

The vast majority of NPPs are equipped with light- and heavy-water-cooled reactors (377 and 49, respectively), which is currently the largest group of nuclear-power reactors in the world, i.e., 426 from 442 or $\sim 96\%$. 424 of these reactors use a subcritical-pressure Rankine cycle with saturated primary steam (at pressures up to 7.8 MPa) and slightly overheated secondary steam (see Fig. 6C), so these NPPs have significantly lower thermal efficiencies (32–38%) compared to those of advanced modern thermal power plants (see Table 2).

The only exceptions are power cycles of Russian SMRs: KLT-40S (two of which are currently in operation) and RITM-200M (Pioro et al., 2019, 2020). These SMRs are equipped with subcritical-pressure Rankine cycles with overheated primary steam, but without a reheat option (see Table 2 and Fig. 10). Due to that, thermal efficiencies of these SMR NPPs are the lowest ones (i.e., 26% and 31%, respectively) compared to those of other light- and heavy-water-cooled reactors NPPs.

Analysis of T-s diagrams and the corresponding NPPs layouts (see Appendix A1 in Pioro (2016)) shows that NPPs with water-cooled reactors have possibly reached their maximum achievable thermal efficiencies (close to 36–38%), because further increase in reactor-coolant pressures (i.e., beyond 15–16 MPa) will lead to a small rise in the coolant saturation temperature (see Fig. 1 in Dragunov et al. (2015)). Moreover, it will lead to a significant decrease in Critical Heat Flux (CHF) at flow boiling (see Fig. 2 in Dragunov et al. (2015)).

Thermal efficiency of an NPP and any thermal power plant is a very important general parameter for comparison of various power plants. Higher thermal efficiency is better, because nuclear or thermal power plant will have less thermal/various emission pollutions per kg of fuel, less fuel per kW h of electricity generated, less cost of kW h, and less cooling water required. Currently, cooling shortfall is a serious concern due to the climate change and more often and more severe dryouts/higher water temperatures in rivers, lakes, and even seas/oceans around the world, etc.

However, it should be stated that in spite of the thermal efficiency being the driving force for advances in thermal and nuclear power plants, quite often other parameters, policies, or conditions influence decisions, which type of reactors/NPPs to build in a country or in a region. As such, Canada develops PHWRs, in particular, CANDU^{®1} reactors, from 1950s, and due to that, up till now, all 19 Canadian nuclear-power reactors are of PHWR type. India, originally a partner with Canada, has quite similar, but now an independent approach, therefore, the vast majority of their reactors are also of PHWR type.

United States and Japan have a number of large nuclear vendors, which, after being in a cooperative license, developed PWRs and BWRs/ABWRs. Therefore, they have only these types of nuclear-power reactors (United States—63 PWRs and 31 BWRs, and Japan—16 PWRs and 17 BWRs). On the other hand, France has only one nuclear vendor, and after terminating an United States cooperation license and stopping gas-reactor builds, now have all their NPPs equipped with only PWRs. Also, it should be mentioned that thermal efficiencies of water-cooled SMRs NPPs are lower than those of modern NPPs equipped with LWRs.

(B) Detailed layout of SFR (BN-600) NPP (based on data from Grigor'ev and Zorin (1988) and Margulova (1995)) (for details, see Pioro (2016)). Secondary steam is reheated with liquid sodium from intermediate loop in preheater. (C) Simplified T - s diagram of subcritical-pressure superheated-steam Rankine cycle with reheat option of SFR (BN-600) NPP. Shown Rankine cycle is typical one for older, i.e., subcritical-pressure thermal power plants, AGR NPPs, and next generation or Generation-IV LFR NPPs (for exact parameters, see Tables 2 and 3, and Pioro (2016)).

Fig. 5 (continued).

However, SMRs will undoubtedly have their unique “niche” applications of being implemented in remote areas, small electrical grids, military facilities, and as floating NPPs (Pioro et al., 2019, 2020; Pioro, 2016).

Current NPPs generate mainly electricity. Just few of them are used for district heating and hot-water supply and for water desalination. However, there are needs for process heat, hydrogen co-generation, etc., which cannot be achieved at modern NPPs due to relatively low temperatures inside reactors, especially, cooled with light and heavy water. Therefore, to increase thermal efficiencies to the level of those at modern advanced thermal power plants and to cover these new needs, the world has to move to high-temperature reactors, such as next generation or Generation-IV reactors (see Pioro, 2016).

Thermal efficiencies of next generation or Generation-IV NPPs

It should be mentioned that thermal-power industry is ahead of nuclear-power one in terms of using advanced power cycles (Pioro, 2016). Due to this next generation or Generation-IV nuclear-power reactors will be connected to combined power cycles, Brayton cycle, or to supercritical-pressure Rankine cycle (for details, see Table 3; Chapter 00301 by A. Stanculescu in this Encyclopedia; GIF (<https://www.gen-4.org/gif/>); and Pioro (2016)). However, in Brayton cycles combustion products will be replaced with helium, nitrogen, mixture of helium and nitrogen, or supercritical-pressure carbon dioxide (for details, see Pioro (2016) and Mahdi et al. (2018)) (Figs. 11–14).

Capacity factor

Another important general parameter of any power plant is a capacity factor.

Net capacity factor of a plant is the ratio of the actual output of a power plant over a period of time (usually, during a year) to its potential output, if it had operated at its full “nameplate” capacity the entire time. Capacity factors vary significantly depending on the type of a plant (for details, see Table 4).

It should be mentioned that, in general, capacity factors can be induced by Mother Nature, i.e., mainly, all renewable-sources power plants, or artificially induced, e.g., for thermal power plants to compensate variations in consumption of electricity and/or generation of electricity with renewable-sources power plants (for details, see Fig. 14); unreliable operation of plant equipment, long-terms for reactor re-fueling, etc.

In terms of capacity factors, NPPs have proven records of high capacity factors up to 100% for new plants, especially, compared to those of renewable-sources power plants (see Table 4). In general, there are two groups of nuclear-power reactors with: (1) Batch refueling (PWRs, BWRs, and SFRs) and (2) Refueling on-line (PHWRs, LGRs, and, partially, AGRs). In previous years, refueling on-

Fig. 6 (A) Simplified layout of typical US Pressurized Water Reactor (PWR) NPP (courtesy of USA NRC) (for details, see [Pioro \(2016\)](#)). (B) Detailed layout of typical PWR (VVER-1000 NPP (winter operation)) (based on data from [Grigor'ev and Zorin \(1988\)](#) and [Margulova \(1995\)](#)) (for details, see [Pioro, 2016](#)). (C) Simplified T - s diagram of subcritical-pressure saturated-steam Rankine cycle with reheat option (secondary steam is reheated with primary steam in preheater) of PWR (VVER-1000) NPP (summer operation): HP, high pressure; LP, low-pressure; MS, moisture separator; SG, steam generator. Shown Rankine cycle is typical one for light- and heavy-water-cooled reactors: PWRs, BWRs, LGRs, and PHWRs (for exact parameters, see [Table 2](#) and [Pioro, 2016](#)).

Fig. 6 (continued).

line allows reactors to run continuously for longer time, and, at that time, it was some advantage of such reactors/NPPs compared to batch-refueling ones. However, nowadays, batch-refueling reactors started to use slightly higher fuel enrichments of up to 5% and higher fuel burnups, which allowed to prolong their continuous operation, and effective NPPs outage management decreased a number of days required for refueling. Therefore, now the advantages of the on-line refueling are not so obvious compared to that of the batch refueling.

How various energy sources generate electricity in a grid can be illustrated based on the Province of Ontario (Canada) system. It should be noted that all, i.e., 19, nuclear-power reactors in Canada are of CANDU®-reactor type, and 18 of these reactors are located in the Province of Ontario (for details, see Pioro et al. (2019) and Pioro (2016)). Currently, the Province of Ontario has completely eliminated coal-fired power plants from its electrical grid. Some of them were closed, others—converted to natural gas. Ontario major installed capacities in 2015 were nuclear (38%), natural gas (29%), hydro (25%), and renewables (mainly wind) (8%). However, electricity was mainly generated by nuclear (60%), hydro (24%), natural gas (8.7%), and renewables (mainly wind) (6.9%).

Fig. 14A shows power generated, and Fig. 14B—capacity factors of various energy sources in Ontario electrical grid in summer (June 17, 2015). Analysis of the data in Fig. 14 shows that a full mix of nuclear, hydro, gas, wind, biofuel, and solar were the major sources for electricity generation (for operation of the Ontario grid with coal-fired power plants, see Pioro (2016) and Pioro and Duffey (2015)).

Electricity that day from midnight till 3.00 a.m. was mainly generated with nuclear, hydro, gas, wind, and biofuel (see Fig. 14A). After 3.00 a.m., biofuel power plants have increased slightly electricity generation followed by hydro and gas-fired power plants due to increased consumption of electricity in the province. Also, at the same time, wind power plants have also slightly increased electricity generation. However, after 7.00 a.m. wind power started to fluctuate and, eventually, decreased significantly. After 6.00 a.m., solar-power plants started to generate electricity.

During a day, hydro, gas-fired and biofuel power plants had variable electricity generation to compensate changes in consumption of electrical energy and variations in generating electricity from wind and solar power plants. After 9 p.m. in the evening, energy consumption started to drop in the province, and at the same time, wind power increased. Therefore, gas-fired, hydro, and biofuel power plants have decreased their energy generation accordingly due to the preferred feed-in-tariffs allocated to wind.

It should be noted that NPPs operated at about 100% of installed capacity providing reliable basic power to the grid. This example shows clearly that any grid that includes NPPs and/or renewable-energy sources must also include “fast-response” power plants such as gas-fired, coal-fired and/or large hydro-power plants to compensate changes in consumption of electrical energy per day and variations in electricity supply by wind and/or solar power plants.

Also, it should be mentioned that in the current chapter only two basic general parameters of power plants were considered. However, there are other important parameters of power plants, which include capital and operational costs, eventually, generated electricity costs, fuel costs, environmental impact, operational term, area covered by a plant, etc.

Conclusions

One of the major parameters of any power plant is efficiency or thermal efficiency. The thermal efficiency is the major driving force for all advances in thermal and nuclear power plants. Ranges of gross thermal efficiencies of modern power plants are as the following: (1) Combined-cycle thermal power plants—up to 62%; (2) Supercritical-pressure coal-fired thermal power plants—up to 55%; (3) Subcritical-pressure coal-fired thermal power plants—up to 43%; (4) Carbon-dioxide-cooled reactor NPPs—up to 42%; (5) Sodium-cooled Fast Reactor (SFR) NPPs—up to 40%; (6) Modern water-cooled-reactor NPPs—30–36% (up to 38%); and (7) Current PWR-SMRs NPPs—26–31%.

However, all current Generation-II and III and oncoming Generation-III⁺ NPPs, especially, those equipped with light- and heavy-water-cooled reactors, are not competitive with modern thermal power plants in terms of thermal efficiency (30–36% (up to 38%) for current NPPs with light- and heavy-water-cooled reactors and up to 55%/62% for supercritical-pressure coal-fired and combined-cycle power plants, respectively).

Comparison of various types of reactors/NPPs showed that there is no reactor design, which will be the best for all the possible parameters. In general, thermal efficiency of an NPP can be one of the important factors to be considered. In this case, higher thermal efficiency is better, because NPP will have less thermal/various emissions pollutions per kg of fuel, less fuel per kW h of electricity generated, less cost of kW h, less cooling water required (which, currently, is a serious concern due to the climate change and more often and more severe dryouts/higher water temperatures in rivers, lakes, and even seas/oceans around the world), etc. Also, higher thermal efficiencies of NPPs make nuclear power more competitive with thermal and other power plants.

Current NPPs are mainly generate electricity. Just few on them are used for district heating and hot-water supply, and for water desalination. However, there are needs for process heat, hydrogen co-generation, etc., which cannot be achieved at modern NPPs due to relatively low temperatures inside reactors, especially, cooled with light and heavy water. Therefore, to increase thermal efficiencies to the level of those at modern advanced thermal power plants and to cover these new needs, the world has to move to high-temperature reactors, such as next generation or Generation-IV reactors.

Another important parameter of any power plant is a capacity factor. It should be mentioned that, in general, capacity factors can be induced by Mother Nature, i.e., mainly, all renewable-sources power plants, or artificially induced, e.g., for thermal power plants to compensate variations in consumption of electricity and/or generation of electricity with renewable-sources power plants (for details, see Fig. 14); unreliable operation of plant equipment, long-terms for reactor re-fueling, etc.

Also, it should be mentioned that in the current chapter only two basic general parameters of power plants were considered, i.e., thermal efficiency and capacity factor. However, there are other important parameters of power plants, which include capital and operational costs, eventually, generated electricity costs, fuel costs, environmental impact, operational term, area covered by a plant, etc.

The major advantages of nuclear power are well-known, including cheap reliable base-load power, high capacity factor, low carbon-dioxide emissions, and minor environmental impact. However, these factors are offset today by a competitive economic disadvantage with cheap natural gas combined-cycle power plants. Hopefully, Generation-IV reactors/NPPs under development will close or reduce the efficiency gap.

Introduction: Electricity generation in the world and selected countries

It is well-known that electricity generation and its consumption are the key factors for advances in industry, agriculture, technology, and the level of living. Table 1 shows clearly a strong dependence of Human Development Index (HDI) (Rows No. 4 and 5) from Electrical-Energy Consumption (EEC) per capita (Row 3); current population is shown in Row 1 (for details, see Pioro et al. (2019, 2020); Pioro (2016); Pioro and Duffey (2015)). Also, robust power industry with diverse energy sources is very important for a country's economic and political independence.

In general, electricity (see Table 1) can be generated from: (1) traditional fuels (i.e., non-renewable sources) such as coal, natural gas, oil, and nuclear utilizing mined resources; and (2) so-called, "renewables" such as hydro, biomass, wind, geothermal, solar, and marine (tidal and wave) power utilizing geotechnical resources.

Today, the main sources for global electrical-energy generation (see Table 1) are: (1) Thermal power—primarily using coal (38.3%) and secondarily using natural gas (22.9%); (2) "Large" hydro-electric power plants (16.3%); and (3) Nuclear power (10.2%). The rest 12.3% of the electrical energy is generated using renewables (wind, biomass, geothermal, solar, and marine energy) (6.6%), oil (3.3%), and other sources (2.4%).

Passive system of containment emergency pressure decrease (condensing system); (2) Active emergency cooling system through heat exchangers of loops I–III; (3) Passive emergency core cooling system (hydraulic accumulators); (4) Active emergency core cooling system from feedwater pumps; (5) Active system for injecting liquid absorber; (6) Active emergency core cooling system from feedwater pumps; (7) Active emergency core cooling system through recirculation pumps; (8) System of reactor caisson filling with water; (9) Containment passive emergency pressure decrease system (bubbling); (10) Active emergency shutdown cooling system (through process condensers); (11) Passive emergency shutdown cooling system; and (12) To atmosphere. (D) Simplified T-s diagram of subcritical-pressure overheated-steam PWR-SMR (KLT-40S) NPP (Akademik Lomonosov floating NPP, Chukotka, Russia). Shown Rankine cycle is typical one for RITM-200M NPP (for exact parameters, see Table 2 and Pioro et al. (2020)). Diagram is prepared based on data available in open literature.

Table 3 Estimated ranges of thermal efficiencies (gross) of Generation-IV NPP concepts (Generation-IV concepts are listed according to thermal-efficiency decrease) (Pioro, 2016).

No	Nuclear power plant	Gross eff. %
1	Very High Temperature Reactor (VHTR) NPP reactor coolant—helium (SCF): $P = 7$ MPa and $T_{in}/T_{out} = 640/1000$ °C; primary power cycle—direct SCP Brayton helium-gas-turbine cycle (however, originally, VHTR concept was intended for hydrogen generation); possible back-up—indirect Brayton or combined cycles (see Fig. 11)	≥ 55
2	Gas-cooled Fast Reactor (GFR) or High Temperature Reactor (HTR) NPP (reactor coolant—helium (SCF): $P = 9$ MPa and $T_{in}/T_{out} = 490/850$ °C; primary power cycle—direct SCP Brayton helium-gas-turbine cycle (see Fig. 12); possible back-up—indirect SCP Brayton or combined cycles (see Fig. 13))	≥ 50
3	SuperCritical Water-cooled Reactor (SCWR) NPP (one of Canadian concepts; reactor coolant—SC light water: $P = 25$ MPa and $T_{in}/T_{out} = 350/625$ °C ($T_{cr} = 374$ °C); direct cycle; SCP Rankine cycle with high-temperature secondary-steam superheat: $T_{out} = 625$ °C; possible back-up—indirect SCP Rankine “steam”-turbine cycle with high-temperature secondary-steam superheat). (For details, see Fig. 3)	45–50
4	Molten Salt Reactor (MSR) NPP (reactor coolant—sodium-fluoride salt with dissolved uranium fuel: $T_{in}/T_{out} = 700/800$ °C; primary power cycle—indirect SCP carbon-dioxide Brayton gas-turbine cycle; possible back-up—indirect Rankine steam-turbine cycle or combined cycles)	~ 50
5	Lead-cooled Fast Reactor (LFR) NPP Russian design BREST-OD-300 ^a : reactor coolant—liquid lead: $P \approx 0.1$ MPa and $T_{in}/T_{out} = 420/540$ °C; primary power cycle—indirect subcritical-pressure Rankine steam cycle: $P_{in} \approx 17$ MPa ($P_{cr} = 22.064$ MPa) and $T_{in}/T_{out} = 340/505$ °C ($T_{cr} = 374$ °C); high-temperature secondary-steam superheat; (for typical T - s diagram, see Fig. 5C); in one of the previous designs of BREST-300 NPP primary power cycle was indirect SCP Rankine “steam” cycle: $P_{in} \approx 24.5$ MPa ($P_{cr} = 22.064$ MPa) and $T_{in}/T_{out} = 340/520$ °C ($T_{cr} = 374$ °C) (For details, see Fig. 3); also, note that power-conversion cycle in a different LFR designs from other countries is based on SCP carbon-dioxide Brayton gas-turbine cycle	~ 41 –43
6	Sodium-cooled Fast Reactor (SFR) NPP Russian design BN-600: reactor coolant—liquid sodium (primary circuit): $P \approx 0.1$ MPa and $T_{in}/T_{out} = 380/550$ °C; liquid sodium (secondary circuit): $T_{in}/T_{out} = 320/520$ °C; primary power cycle—indirect Rankine steam-turbine cycle: $P_{in} \approx 14.2$ MPa ($T_{sat} \approx 337$ °C) and $T_{in\ max} = 505$ °C ($T_{cr} = 374$ °C); secondary-steam superheat: $P \approx 2.45$ MPa and $T_{in}/T_{out} = 246/505$ °C; (For details, see Fig. 5); possible back-up in some other countries—indirect SCP carbon-dioxide Brayton gas-turbine cycle	~ 40

^aBREST-OD-300 is Fast Reactor with “NATural safety”-Test-Demonstration in Russian abbreviations (БРЕСТ-ОД-300, Быстрый Реактор с Естественной безоПасностью—ОПытно—Демонстрационный).

Fig. 11 (A) Simplified layout of 600-MW_{th} VHTR NPP with combined power cycle: Supercritical carbon-dioxide (S-CO₂) Brayton and Rankine cycles (based on figure from Bae et al. (2014)) and (B) Simplified T - s diagrams (Mahdi et al., 2018).

Fig. 12 Simplified layout of 600-MW_{th} GFR concept considered initially by GIF with direct Brayton helium power cycle (Courtesy of GIF) (see also, Pioro, 2016).

Table 1 also lists 13 countries, which have the largest number of nuclear-power reactors/their installed capacities. These countries are listed according to the decreasing population.

Analysis of the data in **Table 1** shows that the world (~38%) and, especially, countries with the largest population, i.e., China (~66%) and India (~75%), as well as Germany (~37%) and South Korea (~42%) rely heavily on coal for the electricity generation. The United States (~39%), Russia (~59%), Japan (~37%), and United Kingdom (~44%) use mainly natural gas or Liquefied Natural Gas (LNG) for electricity generation, which is better than to use coal, but still, for now, we cannot avoid emissions of carbon dioxide and NO_x due to a combustion process. On opposite, France (~72%) and Ukraine (~54%) rely heavily on nuclear power, which is, in general, the lowest emitter of carbon dioxide compared to all other electricity-generating sources including renewables (for details, see Pioro et al., 2019). Canada and Sweden are the only countries from the 13 ones, which rely heavily on the hydro electricity generation ~61% and ~39%, respectively.

Analysis of the data on installed capacities of various power plants in the world (https://en.wikipedia.org/wiki/List_of_largest_power_stations) shows that the 22 largest power plants have installed capacities ranging within 5700–22,500 MW_{el}. Within these power plants the largest group is hydro plants (in total 12) with installed capacities ranging from 5850 and up to 22,500 MW_{el}, six Nuclear Power Plants (NPPs) (installed capacities 5700–7965 MW_{el}) (for now, the largest in the world NPP—Kashiwazaki-Kariwa NPP is not in service after the Fukushima-Daiichi NPP severe accident in March of 2011), 2 coal- and 1 gas-fired thermal power

Fig. 14 Power generated (A) and capacity factors (B) of various energy sources in Ontario (Canada) in hot summer working day—June 17 (Wednesday), 2015 (based on data from <http://ieso.ca/imoweb/marketdata/genEnergy.asp>) (shown here for reference purposes) (Pioro et al., 2019 and Pioro, 2016).

Table 4 Average (typical) capacity factors of various power plants (Pioro et al., 2019; Pioro, 2016; https://en.wikipedia.org/wiki/Capacity_factor).

No.	Power plant type	Locations	Years	Capacity factor %
1	Nuclear	United States	2017	92
		Canada (CANDU®-reactors)	Life-time (average)	87
		Russia	2014	81

		United Kingdom	2015	12
10	Wave	United Kingdom	2015	3

the internal usage of a power plant, which might be not so small (5% or even more). Also, the thermal efficiency is the driving force for advances in thermal power plants and, nowadays, in NPPs.

Analysis of the data listed in Table 2 shows that the top power plants by the thermal efficiency are: (1) Combined-cycle power plants (combination of Brayton gas-turbine cycle and subcritical-pressure Rankine steam-turbine cycle) (for details, see Appendix A1 in Pioro, 2016) with the highest thermal efficiency in the power industry of up to 62%, which means that roughly 2/3 of thermal energy introduced inside the combined power cycle is used for electricity generation, i.e., useful energy (in general, “useful” energy can include electricity; process heat; hot water/steam for heating of buildings, hot-water supply, etc.; and desalination) and only 1/3 of the total energy is lost into environment; and (2) Supercritical-pressure Rankine steam-turbine cycle of coal-fired power plants with up to 55% thermal efficiency (for details, see Appendix A1 in Pioro (2016) and Pioro and Duffey (2007)). Unfortunately, NPPs with subcritical-pressure Rankine steam-turbine cycle have significantly lower thermal efficiencies up to 1.5–2.4 times compared to those of the top thermal power plants.

It is reasonable to compare NPPs with various types of nuclear-power reactors based on thermal efficiencies (for details, see [Table 2](#) and [Figs. 3C, 6C and 8C](#)), where AGR NPPs have the highest thermal efficiency in the nuclear-power industry of up to 42% ([Figs. 2 and 3C](#)), and SFR NPPs—up to 40% ([Fig. 3](#)). Such relatively high thermal efficiencies are due to higher temperatures inside reactors (in AGRs the outlet temperature of the carbon-dioxide reactor coolant is up to 650 °C, and in SFRs with the liquid-sodium reactor coolant—up to 550 °C), adopting subcritical-pressure Rankine cycles with primary and secondary superheated steam and relatively high primary-steam pressures—17 MPa and 14.2 MPa, respectively.

However, the last AGR (only 14 left in United Kingdom) was connected to a grid in 1989, i.e., with no new AGRs have been built for last 32 years. Possible reasons for stopping AGRs in the United Kingdom were the cost, build difficulties (problems with intermediate heat exchangers and thermal insulation), and issues with attaining on-line refueling at full-power plus lower costs alternatives. Therefore, unfortunately, these reactors/NPPs will be never built again.

In terms of SFRs, only two are currently in operation in Russia, and the relatively low boiling point of sodium (882.8 °C) means that these unique fast reactors/NPPs will not possibly have higher thermal efficiencies in the future. Currently, China is finalizing construction of the first China Fast Reactor (CFR-600) and has started construction of another one (<https://www.neimagazine.com/news/newschina-begins-construction-of-second-cfr-600-fast-reactor-8435608>).

The vast majority of NPPs are equipped with light- and heavy-water-cooled reactors (377 and 49, respectively), which is currently the largest group of nuclear-power reactors in the world, i.e., 426 from 442 or ~96%. 424 of these reactors use a subcritical-pressure Rankine cycle with saturated primary steam (at pressures up to 7.8 MPa) and slightly overheated secondary steam (see [Fig. 6C](#)), so these NPPs have significantly lower thermal efficiencies (32–38%) compared to those of advanced modern thermal power plants (see [Table 2](#)).

The only exceptions are power cycles of Russian SMRs: KLT-40S (two of which are currently in operation) and RITM-200M ([Pioro et al., 2019, 2020](#)). These SMRs are equipped with subcritical-pressure Rankine cycles with overheated primary steam, but without a reheat option (see [Table 2](#) and [Fig. 10](#)). Due to that, thermal efficiencies of these SMR NPPs are the lowest ones (i.e., 26% and 31%, respectively) compared to those of other light- and heavy-water-cooled reactors NPPs.

Analysis of *T-s* diagrams and the corresponding NPPs layouts (see Appendix A1 in [Pioro \(2016\)](#)) shows that NPPs with water-cooled reactors have possibly reached their maximum achievable thermal efficiencies (close to 36–38%), because further increase in reactor-coolant pressures (i.e., beyond 15–16 MPa) will lead to a small rise in the coolant saturation temperature (see [Fig. 1](#) in [Dragunov et al. \(2015\)](#)). Moreover, it will lead to a significant decrease in Critical Heat Flux (CHF) at flow boiling (see [Fig. 2](#) in [Dragunov et al. \(2015\)](#)).

Thermal efficiency of an NPP and any thermal power plant is a very important general parameter for comparison of various power plants. Higher thermal efficiency is better, because nuclear or thermal power plant will have less thermal/various emission pollutions per kg of fuel, less fuel per kW h of electricity generated, less cost of kW h, and less cooling water required. Currently, cooling shortfall is a serious concern due to the climate change and more often and more severe dryouts/higher water temperatures in rivers, lakes, and even seas/oceans around the world, etc.

However, it should be stated that in spite of the thermal efficiency being the driving force for advances in thermal and nuclear power plants, quite often other parameters, policies, or conditions influence decisions, which type of reactors/NPPs to build in a country or in a region. As such, Canada develops PHWRs, in particular, CANDU^{®1} reactors, from 1950s, and due to that, up till now, all 19 Canadian nuclear-power reactors are of PHWR type. India, originally a partner with Canada, has quite similar, but now an independent approach, therefore, the vast majority of their reactors are also of PHWR type.

United States and Japan have a number of large nuclear vendors, which, after being in a cooperative license, developed PWRs and BWRs/ABWRs. Therefore, they have only these types of nuclear-power reactors (United States—63 PWRs and 31 BWRs, and Japan—16 PWRs and 17 BWRs). On the other hand, France has only one nuclear vendor, and after terminating an United States cooperation license and stopping gas-reactor builds, now have all their NPPs equipped with only PWRs. Also, it should be mentioned that thermal efficiencies of water-cooled SMRs NPPs are lower than those of modern NPPs equipped with LWRs. However, SMRs will undoubtedly have their unique “niche” applications of being implemented in remote areas, small electrical grids, military facilities, and as floating NPPs ([Pioro et al., 2019, 2020; Pioro, 2016](#)).

Current NPPs generate mainly electricity. Just few of them are used for district heating and hot-water supply and for water desalination. However, there are needs for process heat, hydrogen co-generation, etc., which cannot be achieved at modern NPPs due to relatively low temperatures inside reactors, especially, cooled with light and heavy water. Therefore, to increase thermal efficiencies to the level of those at modern advanced thermal power plants and to cover these new needs, the world has to move to high-temperature reactors, such as next generation or Generation-IV reactors (see [Pioro, 2016](#)).

Thermal efficiencies of next generation or Generation-IV NPPs

It should be mentioned that thermal-power industry is ahead of nuclear-power one in terms of using advanced power cycles ([Pioro, 2016](#)). Due to this next generation or Generation-IV nuclear-power reactors will be connected to combined power cycles, Brayton cycle, or to supercritical-pressure Rankine cycle (for details, see [Table 3](#); Chapter 00301 by A. Stanculescu in this Encyclopedia; GIF

¹CANDU[®]—Registered Trademark of AECL, used under license by Candu Energy Inc., Member of SNC-Lavalin Nuclear Group.

(<https://www.gen-4.org/gif/>); and Pioro (2016)). However, in Brayton cycles combustion products will be replaced with helium, nitrogen, mixture of helium and nitrogen, or supercritical-pressure carbon dioxide (for details, see Pioro (2016) and Mahdi et al. (2018)) (Figs. 11–14).

Capacity factor

Another important general parameter of any power plant is a capacity factor.

Net capacity factor of a plant is the ratio of the actual output of a power plant over a period of time (usually, during a year) to its potential output, if it had operated at its full “nameplate” capacity the entire time. Capacity factors vary significantly depending on the type of a plant (for details, see Table 4).

It should be mentioned that, in general, capacity factors can be induced by Mother Nature, i.e., mainly, all renewable-sources power plants, or artificially induced, e.g., for thermal power plants to compensate variations in consumption of electricity and/or generation of electricity with renewable-sources power plants (for details, see Fig. 14); unreliable operation of plant equipment, long-terms for reactor re-fueling, etc.

In terms of capacity factors, NPPs have proven records of high capacity factors up to 100% for new plants, especially, compared to those of renewable-sources power plants (see Table 4). In general, there are two groups of nuclear-power reactors with: (1) Batch refueling (PWRs, BWRs, and SFRs) and (2) Refueling on-line (PHWRs, LGRs, and, partially, AGRs). In previous years, refueling on-line allows reactors to run continuously for longer time, and, at that time, it was some advantage of such reactors/NPPs compared to batch-refueling ones. However, nowadays, batch-refueling reactors started to use slightly higher fuel enrichments of up to 5% and higher fuel burnups, which allowed to prolong their continuous operation, and effective NPPs outage management decreased a number of days required for refueling. Therefore, now the advantages of the on-line refueling are not so obvious compared to that of the batch refueling.

How various energy sources generate electricity in a grid can be illustrated based on the Province of Ontario (Canada) system. It should be noted that all, i.e., 19, nuclear-power reactors in Canada are of CANDU[®]-reactor type, and 18 of these reactors are located in the Province of Ontario (for details, see Pioro et al. (2019) and Pioro (2016)). Currently, the Province of Ontario has completely eliminated coal-fired power plants from its electrical grid. Some of them were closed, others—converted to natural gas. Ontario major installed capacities in 2015 were nuclear (38%), natural gas (29%), hydro (25%), and renewables (mainly wind) (8%). However, electricity was mainly generated by nuclear (60%), hydro (24%), natural gas (8.7%), and renewables (mainly wind) (6.9%).

Fig. 14A shows power generated, and Fig. 14B—capacity factors of various energy sources in Ontario electrical grid in summer (June 17, 2015). Analysis of the data in Fig. 14 shows that a full mix of nuclear, hydro, gas, wind, biofuel, and solar were the major sources for electricity generation (for operation of the Ontario grid with coal-fired power plants, see Pioro (2016) and Pioro and Duffey (2015)).

Electricity that day from midnight till 3.00 a.m. was mainly generated with nuclear, hydro, gas, wind, and biofuel (see Fig. 14A). After 3.00 a.m., biofuel power plants have increased slightly electricity generation followed by hydro and gas-fired power plants due to increased consumption of electricity in the province. Also, at the same time, wind power plants have also slightly increased electricity generation. However, after 7.00 a.m. wind power started to fluctuate and, eventually, decreased significantly. After 6.00 a.m., solar-power plants started to generate electricity.

During a day, hydro, gas-fired and biofuel power plants had variable electricity generation to compensate changes in consumption of electrical energy and variations in generating electricity from wind and solar power plants. After 9 p.m. in the evening, energy consumption started to drop in the province, and at the same time, wind power increased. Therefore, gas-fired, hydro, and biofuel power plants have decreased their energy generation accordingly due to the preferred feed-in-tariffs allocated to wind.

It should be noted that NPPs operated at about 100% of installed capacity providing reliable basic power to the grid. This example shows clearly that any grid that includes NPPs and/or renewable-energy sources must also include “fast-response” power plants such as gas-fired, coal-fired and/or large hydro-power plants to compensate changes in consumption of electrical energy per day and variations in electricity supply by wind and/or solar power plants.

Also, it should be mentioned that in the current chapter only two basic general parameters of power plants were considered. However, there are other important parameters of power plants, which include capital and operational costs, eventually, generated electricity costs, fuel costs, environmental impact, operational term, area covered by a plant, etc.

Conclusions

One of the major parameters of any power plant is efficiency or thermal efficiency. The thermal efficiency is the major driving force for all advances in thermal and nuclear power plants. Ranges of gross thermal efficiencies of modern power plants are as the following: (1) Combined-cycle thermal power plants—up to 62%; (2) Supercritical-pressure coal-fired thermal power plants—up to 55%; (3) Subcritical-pressure coal-fired thermal power plants—up to 43%; (4) Carbon-dioxide-cooled reactor NPPs—up to 42%; (5) Sodium-cooled Fast Reactor (SFR) NPPs—up to 40%; (6) Modern water-cooled-reactor NPPs—30–36% (up to 38%); and (7) Current PWR-SMRs NPPs—26–31%.

However, all current Generation-II and III and oncoming Generation-III⁺ NPPs, especially, those equipped with light- and heavy-water-cooled reactors, are not competitive with modern thermal power plants in terms of thermal efficiency (30–36% (up to 38%) for current NPPs with light- and heavy-water-cooled reactors and up to 55%/62% for supercritical-pressure coal-fired and combined-cycle power plants, respectively).

Comparison of various types of reactors/NPPs showed that there is no reactor design, which will be the best for all the possible parameters. In general, thermal efficiency of an NPP can be one of the important factors to be considered. In this case, higher thermal efficiency is better, because NPP will have less thermal/chemical emissions/pollutions per kg of fuel, less fuel per kW h of electricity generated, less cost of kW h, less cooling water required (which, currently, is a serious concern due to the climate change and more often and more severe dryouts/higher water temperatures in rivers, lakes, and even seas/oceans around the world), etc. Also, higher thermal efficiencies of NPPs make nuclear power more competitive with thermal and other power plants.

Current NPPs are mainly generate electricity. Just few on them are used for district heating and hot-water supply, and for water desalination. However, there are needs for process heat, hydrogen co-generation, etc., which cannot be achieved at modern NPPs due to relatively low temperatures inside reactors, especially, cooled with light and heavy water. Therefore, to increase thermal efficiencies to the level of those at modern advanced thermal power plants and to cover these new needs, the world has to move to high-temperature reactors, such as next generation or Generation-IV reactors.

Another important parameter of any power plant is a capacity factor. It should be mentioned that, in general, capacity factors can be induced by Mother Nature, i.e., mainly, all renewable-sources power plants, or artificially induced, e.g., for thermal power plants to compensate variations in consumption of electricity and/or generation of electricity with renewable-sources power plants (for details, see Fig. 14); unreliable operation of plant equipment, long-terms for reactor re-fueling, etc.

Also, it should be mentioned that in the current chapter only two basic general parameters of power plants were considered, i.e., thermal efficiency and capacity factor. However, there are other important parameters of power plants, which include capital and operational costs, eventually, generated electricity costs, fuel costs, environmental impact, operational term, area covered by a plant, etc.

The major advantages of nuclear power are well-known, including cheap reliable base-load power, high capacity factor, low carbon-dioxide emissions, and minor environmental impact. However, these factors are offset today by a competitive economic disadvantage with cheap natural gas combined-cycle power plants. Hopefully, Generation-IV reactors/NPPs under development will close or reduce the efficiency gap.

Current status and future trends in the world nuclear-power industry

Nuclear power without used-fuel reprocessing and recycling is often considered to be a non-renewable energy source like the mined fossil fuels, such as coal, oil, and natural gas. Moreover, the resources of naturally occurring fissile fuels (uranium and thorium) are

limited in extent, and geographically concentrated in regions of relatively lower population. However, nuclear resources can be used for significantly longer time than some fossil fuels, and in some cases almost indefinitely, if recycling of unused or low burn-up uranium fuel, thorium-fuel resources, and fast-neutron-spectrum reactors that literally can “breed” plutonium are used.

Current statistics on all world nuclear-power reactors connected to electrical grids are listed in **Tables 1–6** and shown in **Figs. 1–4**. Statistical data from previous years are shown in [Pioro et al. \(2019, 2020\)](#), [Pioro and Duffey \(2015\)](#), and [Handbook of Generation IV Nuclear Reactors \(2016\)](#). **Table 6** lists current activities worldwide on new nuclear-power-reactors build, and **Tables 7a and 7b** - basic parameters of various nuclear-power reactors and thermal efficiencies of the corresponding Nuclear Power Plants (NPPs), respectively.

The largest group of nuclear-power reactors by type is PWRs (302 from 442 reactors or 68% of the total number), and quite a significant number of Pressurized Water Reactors (PWRs) are planned to be built (about 39 (+35?)) (for details, see **Table 1**). **Fig. 1** shows the data from **Table 1** in the form of sector diagrams for a number of reactors by type and by installed capacities. The second largest group of reactors is Boiling Water Reactors (BWRs)/Advanced BWRs (ABWRs) (63 reactors or 14% of the total number). The third group is Pressurized Heavy-Water Reactors (PHWRs) (49 reactors or 11% of the total number). Considering the number of forthcoming reactors, the number of BWRs/ABWRs and PHWRs will decrease globally within next 20–25 years. Furthermore, within next 10–15 (maximum 20) years or so, all Light-water-cooled Graphite-moderated Reactors (LGRs) and Advanced Gas-cooled Reactors (AGRs) (carbon-dioxide-cooled) will be shut down forever.

Table 2 lists average, maximum, and minimum installed capacities of nuclear-power reactors of the world of various types (values were rounded to nearest 0 or 5). Analysis of the data in **Table 2** shows that the largest reactor by installed capacity is 1660-MW_{el} PWR (EPR, Generation-III⁺, Areva design, France) (two EPRs are in operation in China and more are under construction in several countries), and the smallest one is a 10-MW_{el} LGR (EGP, former USSR design) (three EGPs are in operation in Russia, but all of them will be shut down in several years).

Table 3 lists a number of nuclear-power reactors connected to grid by selected nations (13 nations with the largest number of nuclear-power reactors/their installed capacities ranked by installed capacities). Analysis of the data in **Table 3** shows that real

Table 1 Number of nuclear-power reactors connected to electrical grid and forthcoming units as per March 2021 (based on data from [Nuclear News \(2021\)](#); <http://www.world-nuclear.org/>; and <https://pris.iaea.org/pris/>) and prior to Japan earthquake and tsunami disaster (based on data from [Nuclear News \(2011\)](#)).

Rank by No	Reactor type (% of total reactors/average installed capacity)	No. of units		Installed capacity, GW _{el}		Forthcoming units	
		As of Mar. 2021	Before Mar. 2011	As of Mar. 2021	Before Mar. 2011	No. of units	GW _{el}
1	Pressurized Water Reactors (PWRs) (68%/955 MW _{el})	302 ↑	268	288 ↑	248	39+35?	45+37? ^a
2	Boiling Water Reactors (BWRs) or Advanced BWRs (14%/1030 MW _{el})	63 ↓	92	65 ↓	84	4?	5.3?

Data for all countries with nuclear-power reactors are listed in Table 4.

Explanations to Table 3:

Arrows mean decrease or increase in a number of reactors.

^aPWRs.

^bNo of LGRs.

^cLMFBRs.

^dAs of October 2020, only nine PWRs were in operation.

^eAGRs.

nuclear “renaissance” is in China (36 reactors built and put into operation within past 9 years), in Russia (addition of 6 reactors), in South Korea (addition of 4 reactors), and in India (addition of 4 reactors). Meanwhile, the most significant drop in a number of reactors is in Japan (21 reactors were shut down) (only about 9 reactors out of 33 are currently in operation), in Germany (11 reactors), in USA (9 reactors), in UK (4 reactors), in Canada (3 reactors), and in Sweden (3 reactors). In addition, Canada, Germany, and Sweden have no plans to build new reactors. It should be noted that, in spite of, outstanding achievements in nuclear-power industry, especially, in China, and, partially, in India, electricity share by nuclear power is very small, i.e., in China - only 4.8% and in India - 2.7%.

Table 4 lists a number of nuclear-power reactors connected to grid or to be connected to grid in a reasonable time by all countries in the world. Analysis of the data in Table 4 shows that, currently, 33 countries in the world have operating nuclear-power reactors (within these countries: 20 plan to build new reactors, and 13 don't plan to build new reactors) and 3 countries without nuclear-power reactors (Bangladesh, Egypt, and Turkey) are working towards introducing nuclear energy on their soils.

Also, in addition to data in Tables 1–4, Fig. 2 shows a number of nuclear-power reactors in the world connected to grid (as per July, 2020) vs. years of their commercial operation (Fig. 2A) and their installed capacities (Fig. 2B). And Fig. 3 shows a number of nuclear-power reactors in the USA connected to grid (as per July, 2020) vs. years of their commercial operation.

Analysis of the data in Fig. 2 shows that the Chernobyl NPP accident (April 26, 1986), which had happened with the RBMK-1000 – LGR (former USSR design), has forced Ukraine to shut down this NPP, and Russia – to cancel any further R&D and construction of new LGRs. In the same way, a small number of BWRs/ABWRs planned to be built is due to the Fukushima-Daiichi NPP severe accident, which had happened with older design BWRs in March of 2011. However, it should be mentioned that all nuclear vendors, of course, including BWRs and ABWRs, have updated their designs with additional features/systems to enhance safety based on lessons learned from all nuclear accidents.

In the case of the USA (see Fig. 3), their nuclear industry was hit quite hard by the Three Mile Island NPP accident and right after that by the Chernobyl NPP accident, which, eventually, decreased the number of reactors built and connected to grid to only six per last 25 years.

Therefore, the history of nuclear-power industry shows that nuclear accidents, especially, severe ones, can override any advantages of various reactors' types, and significantly affect future builds of certain types of reactors, e.g., LGRs and BWRs, or even all types of reactors. We have to remember that one more severe accident somewhere in the world can and does adversely affect the whole nuclear-power industry and broader societal acceptance. Due to this, we must continuously to enhance safety of all nuclear-power reactors.

Fig. 4 shows a number of nuclear-power reactors in the world by installed capacity as per August, 2020. Analysis of the data in this Figure shows that the largest group of reactors is within the range of installed capacities from 900 MW_{el} and up to 999 MW_{el}.

Table 4 Number of nuclear-power reactors connected to electrical grid and forthcoming units as per March 2021 (based on data from [Nuclear News](https://www.nuclear-news.org/) (2021); <http://www.world-nuclear.org/>; and <https://pris.iaea.org/pris/>).

Countries planning to build new reactors are in bold.

Summary: 33 countries have operating nuclear-power reactors; 20 countries from these 33 and 3 countries without reactors plan to build new nuclear-power reactors (in bold color). In addition, 30 countries are considering, planning, or starting nuclear-power programs, and about 20 countries have expressed their interest in nuclear power.

Explanations to Table 4.

^a? – Means “Commercial start date – indefinite” ([Nuclear News](https://www.nuclear-news.org/), 2021).

^bGCR is a helium-cooled reactor – High Temperature Reactor Pebble-bed Modular (HTR-PM) (China).

^cAs of October 2020, only nine reactors were in operation.

However, oncoming reactors of Generation-III⁺, usually, have higher installed capacities compared to those of Generation-III reactors, i.e., within the range of 1100 MW_{el} and up to 1660 MW_{el} (the exception is Small Modular Reactors (SMRs)).

It should be mentioned that globally current successes in nuclear-power industry are far away from previous “glorious” days, when ~80 and ~120 reactors have been built and connected to grid within 1980–1984 and 1985–1989, respectively (see Fig. 2A). Just within last 5 years, i.e., from 2015–2019, about 40,000 MW_{el} of new installed capacities have been added, which match the same amount added within 1975–1979 (see Fig. 2B).

Table 5 Latest years when various types of reactors have been built and connected to grid (based on data from [Nuclear News \(2021\)](#)).

No.	Type of reactor	Model	Reactor supplier	Country	Installed capacity, MW _{el}	Year	Reactor age ^a , years
1	PWR	VVER-1200	ASE	Belorus'	1109	2020	1
		HPR	CNNC	China	1000	2020	1
		ACPR-1000			1000	2020	1
		EPR	Areva		1660	2019	2
		VVER-1200	AEP	Russia	1085	2021	0.5
		KLT-40S (2 SMRs)	OKBM		32	2019	2

2	BWR	ABWR	Hitachi	Japan	1108	2006	15
3	PHWR	PHWR-700	Owner	India	630	2021	0.5
4	AGR	AGR	NNC	UK	605	1989	32
5	LGR	RBMK-1000	MTM	Russia	925	1990	31
6	LMFBR	BN-800	OKBM	Russia	820	2016	5

Reactors built before 1995, i.e., 25 and more years old are in red and *Italic*.

^aReactors age shown for year 2021.

Table 6 Current activities worldwide on new nuclear-power-reactors build (based on data from [Nuclear News \(2021\)](#)).

No	Country/Nuclear supplier	Countries, which are looking forward for new builds (No. of possible units)
1	Russia/Rosatom (outside Russia - ASE (AtomStroyExport) (Nuclear-power activities are supported by Russian government)	Russia (5 + 3?), Bangladesh (2), Belarus (1), China (2 + 2?), Egypt (1 + 3?), Finland (1), Hungary (2?), India (2 + 2?), Iran (2), and Turkey (4): In total: 22 + 10? = 32
2	China/Various vendors (Nuclear-power activities are supported by the Chinese government)	China (9 + 14? ^a), Pakistan (3?), Romania ^b (2? CANDU [®] reactors): In total: 9 + 19? = 28
3	S. Korea/Doosan and KEPCO	S. Korea (4) and UAE (3): In total: 7
4	India/Various vendors	India (4+3?): In total: 7
5	France/Framatome	Finland (1), France (1?), and UK (2): In total: 3 + 1? = 4
6	USA/GE and Westinghouse	USA (2) and Taiwan (2?): In total: 2 + 2? = 4
7	Czech Rep./Skoda	Slovakia (2), Ukraine (2?): In total: 2 + 2? = 4
8	Japan/Toshiba + Hitachi	Japan (2?): In total: 2?
9	Canada/AECL (Candu Energy, Inc.) together with CGNPC (China)	Romania ^b (2? CANDU [®] reactors): In total: 2?
10	Germany/KWU (KraftWerk Union AG)	Brazil (1?): In total: 1?
11	Argentina/CNEA (Comisión Nacional de Energía Atómica)	Argentina (1?): In total: 1?

^a? - Means "Commercial start date – indefinite" ([Nuclear News, 2021](#)).

^bTwo CANDU[®] reactors in Romania for the Cernavoda NPP are a joint venture proposal from China and Canada.

Table 5 lists latest years, when various types of reactors have been built and connected to grid. The latest AGR (carbon-dioxide-cooled) in UK was connected to grid in 1989, i.e., no new AGRs have been built for last 31 years. And, unfortunately, as it was mentioned before, these reactors/NPPs will never be built again.

Table 6 lists current activities in various countries worldwide on new nuclear-power-reactors build. Analysis of the data in **Table 6** clearly shows that Russia and China are the front runners in new nuclear builds in their countries and abroad, largely because both governments provide significant political and long-term support with various funds for nuclear-power R&D and for their government-controlled nuclear vendors, as, also, do South Korea and France, especially, to build NPPs abroad plus credits and other incentives for foreign buyers to introduce nuclear power.

Fig. 1 Nuclear-power reactors of the world (based on data from [Table 1](#) and [Nuclear News \(2021\)](#); <http://www.world-nuclear.org/>; and <https://pris.iaea.org/pris/>): (A) connected to grid – (a₁) by type and (a₂) by installed capacities; and (B) planned to be built (optimistic approach, i.e., including those under?) – (b₁) by type and (b₂) by installed capacities.

The last several years were very important for the nuclear-power industry of the world. Russia put into operation a number of Generation-III⁺ VVERs (PWR – VVER-1200) and the SFR – BN-800 reactor in 2016 and continues to lead the SFR technologies in the world ([Pioro et al., 2019](#); [Handbook of Generation IV Nuclear Reactors, 2016](#)).

China put into operation many reactors/NPPs including the largest in the world Generation-III⁺ PWR – EPR (Areva design) with amazing installed capacity of 1660 MW_{el}. In addition, several AP1000 reactors (Westinghouse design) ([Friedman, 2019](#)), also, a Generation-III⁺ design, were put into operation in China first time in the world ([Nuclear News, 2021](#)). In general, Generation-III⁺ water-cooled reactors/NPPs have enhanced safety and can reach slightly higher thermal efficiencies up to 36–37% (38%) compared to those of Generation-III water-cooled reactors/NPPs (the exception is SMRs). Also, China put into operation the Hua-long One reactor or HPR-1000 – a domestically developed Generation-III reactor design, and plan to put into operation first in the world Gas-Cooled Reactor (GCR) – a helium-cooled reactor: High Temperature Reactor Pebble-bed Modular (HTR-PM) in 2021 plus two SFRs – China Fast Reactors (CFR-600) within next several years.

South Korea put into operation several their Generation-III⁺ APR-1400 (Doosan design) on their soil, another APR-1400 (KEPCO) in UAE, and plans to put six more these reactors into operation soon: 3 inside country and 3 in UAE ([Nuclear News, 2021](#)).

Fig. 2 Number of nuclear-power reactors in the world connected to grid (as per July, 2020) vs. years of their commercial operation (A) and their installed capacities (B) (based on data from Nuclear News (2021); <http://www.world-nuclear.org/>; and <https://pris.iaea.org/pris/>) (for previous data, see Pioro et al. (2019) and Handbook of Generation IV Nuclear Reactors (2016)).

Fig. 3 Number of nuclear-power reactors in the USA connected to grid (as per July, 2020) vs. years of their commercial operation (based on data from Nuclear News (2021); <http://www.world-nuclear.org/>; and <https://pris.iaea.org/pris/>).

India put into operation their latest domestically developed design of PHWR – PHWR-700 in January of 2021.

Current trend in new builds is to build Generation-III⁺ reactors, mainly PWRs. Another trend, which just has appeared, is to build SMRs with installed capacities up to 300 MW_{el} for applications in remote areas, small electrical grids, military facilities, and as floating NPPs; and first two SMRs are 35-MW_{el} PWRs installed on a floating barge, so-called, Floating Nuclear Thermal-Power Plant (FNThPP) by the name of Academician Lomonosov (Russia) (for details, see Tables 7a and 7b, and Pioro et al. (2019, 2020)). Also, in 2021, Rosatom will begin work on a site of the future SMR NPP, which is planned to be built in Yakutia. The SMR will be a RITM-200 ship-based reactor (<https://www.neimagazine.com/news/newsrosatom-to-being-work-on-land-based-smr-8436408>).

Fig. 4 Number of nuclear-power reactors in the world by installed capacity as per July, 2020 (based on data from [Nuclear News \(2021\)](http://www.world-nuclear.org/); <http://www.world-nuclear.org/>; and <https://pris.iaea.org/pris/>). For better understanding of this Figure, the largest number of reactors have installed capacities within the range of 900–999 MW_{el}. Generation-III⁺ reactors, usually, have installed capacities from 1,100 and up to 1,660 MW_{el} (exception is SMRs).

Technical considerations of various types of nuclear-power reactors

Basic parameters of all current reactors' types are listed in [Table 7a](#), and their power cycles – in [Table 7b](#) (for other details, see also Appendix A1 in [Handbook of Generation IV Nuclear Reactors \(2016\)](#)). It should be stated here that there is no such term as “the best” reactor design by all features or parameters. Each reactor design has some pros and cons.

Analysis of the basic parameters of current reactors (see [Tables 7a and 7b](#)) shows that various types of reactors have the following differences:

By neutron spectrum

- 1) Thermal spectrum - vast majority of reactors, i.e., 440 from 442 or 99.5%, which includes Light Water Reactors (LWRs) (PWRs and BWRs/ABWRs), PHWRs, LGRs; and AGRs; and
- 2) Fast spectrum – LMFBRs, i.e., SFRs - two Russian BN-600 and BN-800 reactors. In general, fast reactors are considered to be the future of nuclear-power industry, because fast-neutron-spectrum reactors can “breed” plutonium and can reprocess radioactive wastes. However, fast reactors require higher enrichment of nuclear fuel compared to that of thermal-spectrum reactors (see [Table 7a](#)), and, for now, light water is not considered as a reactor coolant in such reactors. Due to that, there are some limitations, which reactor coolant can be used in fast reactors (currently, sodium, lead, lead-bismuth, helium, and molten salt are considered). A number of nuclear-power advanced countries have tried to develop fast-reactors technologies, but, as of today, only Russia has two operating SFRs.

By reactor coolant and moderator

- 1) Reactor coolants: (a) the most widely used – light water (LWRs and LGRs); (b) heavy water (PHWRs); (c) carbon dioxide (AGRs); and (d) liquid sodium (SFRs).
- 2) Moderator: (a) light water used in LWRs, and there is no separation between reactor coolant and moderator; (b) heavy water in PHWRs, and here reactor coolant and moderator are separated with fuel channels, i.e., reactor coolant is inside a fuel channel and moderator - outside; (c) graphite in LGRs, and here reactor coolant and moderator are separated with fuel channels; (d) graphite in AGRs and here graphite is in contact with reactor coolant; and (e) there is no moderator in fast reactors, i.e., in SFRs.

Properties of various reactor coolants and comparison of heat transfer coefficients in various reactors are shown in [Handbook of Generation IV Nuclear Reactors \(2016\)](#). Comparison of light- and heavy-water thermophysical properties is shown in [Petriw et al. \(2019\)](#) and [Sabir et al. \(2019\)](#).

Table 7a Basic parameters of all current reactors' types (based on data from [Handbook of Generation IV Nuclear Reactors \(2016\)](#) and <http://www.world-nuclear.org/>).

No	Reactor type	Fuel bundle orientation	Sheath (cladding) material ^a	Neutron spectrum	Reactor		Reactor coolant		Refueling	Fuel ^b	Fuel enrichment (%)	HTC ^c (kW/m ² K)
					Coolant	Moderator	P, MPa	T (°C)				
1	PWR	RPV	Vert.	Zr	Th.	H ₂ O	15–16.2	295 → 330	Batch	UO ₂	3–5	~30
	SMR KLT-40S	RPV	Vert.	Zr	Th.	H ₂ O	12.7	280 → 316	Batch	UO ₂	18.6	–
2	BWR	RPV	Vert.	Zr	Th.	H ₂ O	7.2	287.7	Batch	UO ₂	~2	~60
3	PHWR (CANDU®)	PCh	Hor.	Zr	Th.	D ₂ O	11 → 10	260 → 310	On-line	UO ₂	0.7	~50

5	LGR (RBMK)	PCh	Vert.	Zr	Th.	H ₂ O	6.9	284.9	On-line	UO ₂	2–2.4	~60
6	LMFBR (BN-800)	V	Vert.	SS	Fast	Na	~0.1	354 → 547	Batch	MOX	17/20/24	55–85

^aZr – Zirconium alloys; SS – Stainless Steel.

^bCommonly used fuel.

^cHeat Transfer Coefficients (HTCs) are approximate values, shown just for reference purposes.

^dCANDU®-reactor moderator has $P = \sim 0.1$ MPa at the top of calandria vessel and $T = \sim 70$ °C.

^eConcrete RPV.

^fAGRs were designed to be refueled on-line. However, it was found that during refueling at full power fuel assemblies can vibrate, due to that the on-line refueling was suspended from 1988 till the mid-1990s. Nowadays, only refueling at a part load or in shut-down state is now undertaken in AGRs.

Table 7b Basic parameters of all current reactors' types power cycles (based on data from [Handbook of Generation IV Nuclear Reactors \(2016\)](#)).

No	Reactor type	Cycle ^a	No of loops	Rankine-cycle parameters						Thermal efficiencies (gross), %
				Primary steam			Secondary-steam reheat			
				P _{in} , MPa	T _{in} , °C	Steam	P _{in} , MPa	T _{in} , °C	Steam	
1	PWR	Indirect	2	7.72	292.5	Saturated	2	265	Overheated	Up to 38
	SMR KLT-40S	Indirect	2	3.72	290	Overheated	N/A			Up to 26
2	BWR	Direct	1	7.2	287.7	Saturated	1.7	258	Overheated	Up to 34
3	PHWR (CANDU®)	Indirect	2	4.7	260.1	Saturated	~1.2	240	Overheated	Up to 34
4	AGR	Indirect	2	17	560	Superheated	4	560	Superheated	Up to 42
5	LGR (RBMK)	Direct	1	6.9	284.9	Saturated	~0.3	~263	Overheated	Up to 33
6	LMFBR (BN-800)	Indirect	3 ^b	14.2	505	Superheated	2.5	505	Superheated	Up to 40

For more details, see [Handbook of Generation IV Nuclear Reactors \(2016\)](#).

^aAll current reactors connected to Rankine steam cycle (light-water working fluid).

^bBN-800 has 3 loops: (1) liquid sodium circulating inside reactor; (2) intermediate loop with liquid sodium; and (3) water-steam in Rankine cycle.

By pressure-boundary design

- 1) Reactor pressure vessel (RPV) - vast majority of reactors, i.e., 365 LWRs (RPVs made of steel) and 14 AGRs (RPVs made of concrete) or in total 86% of all reactors. In general, RPV of LWRs have two levels of pressures: (1) PWRs – 15 – 16 MPa (older reactors, e.g., VVER-440, and modern PWR SMR KLT-40S have pressures within 12–13 MPa); and (2) BWRs – around 7 MPa. AGRs carbon-dioxide cooled have pressure around 4 MPa.
- 2) Vessel reactors – two Russian SFRs, because pressure above the pool of liquid sodium is close to the atmospheric one; and
- 3) Pressure-channel reactors – 49 PHWRs (pressure up to 11 MPa (e.g., in CANDU[®] reactors) and 12 LGRs (pressure about 6–7 MPa) or in total 14% of all reactors.

Which pros and cons we have for these different pressure-boundary designs:

Pressure vessel (PV) contains reactor core, i.e., bundle strings or fuel-elements (rods) assemblies, which oriented vertically. Pressure vessel has an upper cover and internal insert to guide reactor-coolant flow downwards from the inlet through the gap between the reactor vessel and after that upward through the reactor core to the outlet. Pressure-vessel wall thickness depends mainly on inside pressure and internal diameter of a pressure vessel, and can be for: (1) VVER-1000: Pressure around 16 MPa and ID = 4.14 m - wall thickness ~19 cm; (2) US PWR: Pressure around 16 MPa and ID = 3.96 m - wall thickness - ~22 cm; and (3) US BWR: Pressure around 7 MPa and ID = 6.4 m - wall thickness - 15 cm. Therefore, a pressure vessel is a very important part in a reactor. Due to the three severe nuclear accidents a number of pressure-vessel manufacturing plants in the world were closed or transferred to another production affecting a maximum number of pressure vessels, which can be manufactured in the world. Also, some of these RPV manufacturing plants are oriented only to a certain nuclear vendor, e.g., Russian Atommasht (“АТОММАШ”) for VVER RPVs.

Traditionally, PHWRs are pressure-channel or pressure-tube reactors. In particularly, CANDU[®] reactors have horizontal orientation of fuel channels. Due to small OD of fuel channels, many plants worldwide can manufacture them.

By power cycle

Currently, all nuclear-power reactors are connected to subcritical-pressure Rankine steam-turbine cycles. The vast majority of NPPs equipped with AGRs, LMFBFRs, PWRs, and PHWRs (367 reactors from 442 or 83%) have, so-called, an indirect Rankine cycle, which includes a double loop (AGR, PWRs, and PHWRs): (1) reactor-coolant circulation loop, which includes PV with reactor core, circulation pumps, and steam generators (all of these equipment are located inside a containment building), and Rankine-cycle loop; and (2) triple loop (LMFBFRs – SFRs), which includes a primary loop - reactor vessel with fueled core, circulation pumps, and heat exchangers; intermediate loop with liquid sodium as the working fluid, circulation pump(s), and steam generator(s); and Rankine-cycle loop.

In general, the indirect cycle in which reactor coolant circulates only inside a containment building enhances reactor safety. However, this cycle requires steam generators or heat exchangers through which ~30–40 °C of a temperature difference is usually lost (as such, for PWRs (double loop) - APR-1400: Reactor outlet $T = 324$ °C, steam-generator saturated steam $T_{\text{out}} = 285$ °C, and $\Delta T = \sim 40$ °C; for EPR - $\Delta T = \sim 35$ °C; in terms of SFR – BN-800 (triple loop): Inside reactor $T_{\text{max Na}} = 547$ °C; inside intermediate loop $T_{\text{max Na}} = 505$ °C; and superheated steam $T_{\text{max}} = 490$ °C, and $\Delta T = \sim 57$ °C).

Therefore, in general, the direct cycle is considered to be more efficient from the thermodynamics point of view. Actually, Generation-III⁺ ABWRs have reached levels of pressures up to 7.2 MPa and saturated steam temperature of 287.7 °C (NPP thermal efficiency of about 34%). However, Generation-III⁺ PWRs, in particular, the largest in the world 1660-MW_{el} EPRs, have reached saturation-steam pressures close to 7.8 MPa and corresponding to that $T_{\text{sat}} = 293.3$ °C in the Rankine cycle. Therefore, as of today, NPPs with advanced PWRs have reached thermal efficiency of 36%–37% (38%), which is the highest thermal efficiency among all NPPs equipped with light- and heavy-water reactors.

Based on the above mentioned and accounting that AGRs and LGRs will never be built again, these two reactors types will not be considered in the following comparison. Also, SFRs will not be compared to PWRs/BWRs/PHWRs, because only two of them are in operation in Russia, and just a couple of them are planned to be built in other countries in the future.

Therefore, first comparison is PWRs vs. BWRs (see Table 8).

The second comparison is PWRs vs. PHWRs (CANDU-type reactors) (see Table 9), and Table 10 lists technical and deployment advantages and disadvantages of PHWR-type reactors.

One of the unique features of the CANDU[®]-reactor design is its ability to operate with alternative fuels such as a Recovered Uranium (RU) from the reprocessing of LWR spent fuel, MOX (80% UO₂ and 20% PuO₂), and thorium-based fuels, in addition to the conventional natural-uranium fuel.

In summary, Table 11 provides an overview of a possible “top ten” listing of the Pros (Advantages) and Cons (Disadvantages) for just the five principle general types of classes of reactors still actively involved or being considered in and for the power and energy markets. This Table 11 simply contrasts and compares the possible claims and issues for the generic PWR, BWR, PHWR, SFR, and SMR types, but without any distinction or differentiation between the multitude of design details and engineering variations, which have been illustrated in this chapter.

And, possibly, the final feature, which influences a decision for implementation of a type of reactor, is reactors/NPPs generation changing due to technological advances, accumulated operational knowledge, and design evolutions. Currently, we have nuclear-power reactors mainly of Generation-III. However, from 1990s, reactors of Generation-III⁺ have been built. The first ones were

Table 8 Major similarities and differences between PWRs vs. BWRs (for details, see Tables 2, 5, and 7a and 7b).

No.	Major features	
	PWRs	BWRs
1	Reactor design – reactor pressure vessel	
	Pressures up to 15–16 MPa	Pressures up to 7.2 MPa
	BWR RPV diameter and height can be larger than those in PWRs, but wall thickness is smaller	
	Bundle strings (assemblies) quite similar with vertical orientation and a large number of fuel elements (rods)	
	Control and shut-down rods installed from the top of RPV;	Control and shut-down rods installed from bottom of RPV;
	Control rods are moved with electrical motors; Shut-down rods are kept in the upper position with magnetic lock, dropped down by gravity force (passive safety system)	Control and shut-down rods are moved with electrical motors or/and hydraulic mechanism
	Batch refueling	
2	Fuel enrichment of 3–5% (can be up to 20% for SMRs)	Fuel enrichment of 1.9–2%
	Reactor coolant and moderator – light water, no separation between them	
	Non-boiling reactor coolant	Boiling reactor coolant
	Small changes of water density from inlet to outlet of RPV	Significant changes of water density from inlet to outlet of RPV
	At the RPV outlet – subcooled water with maximum temperatures up to $\sim 330^\circ\text{C}$ or $\sim 15\text{--}25^\circ\text{C}$ below saturation temperature	At the RPV outlet – saturated water-steam mixture with maximum temperatures up to 287.7°C
3	Wide range of installed capacities from 30 MW _{el} (SMRs) and up to 1660 MW _{el}	Smaller range of installed capacities from 150 MW _{el} and up to 1435 MW _{el}
4	Power cycle – subcritical-pressure Rankine steam-turbine cycle	
	Indirect (double loop) with steam generators	Direct
5	Thermal efficiency up to 37% (38%)	Thermal efficiency up to 34%

Table 9 Major differences and similarities between PWRs vs. PHWRs (CANDU-type reactors) (for details, see Tables 2, 5, and 7a and 7b).

No.	Major features	
	PWRs	CANDU®-type reactors
1	Pressure vessel	Pressure channel or pressure tube
2	Vertical bundle strings	Horizontal fuel channels
3	Relatively long bundle strings (~ 4 m)	Short bundles (495.3 mm each, 12 bundles per channel)
4	Bundle-string cross section - square or hexagonal	Bundle cross section - circular
5	Large number of fuel elements (rods) in bundle string, e.g., 17×17	Relatively small number of fuel elements (rods) in bundle - usually, 37 el., proposed 43 el.
6	Reactor coolant/moderator – H ₂ O (light water), no separation between them	Reactor coolant – D ₂ O (heavy water), Moderator - D ₂ O (heavy water), reactor coolant - inside fuel channel, moderator - outside
7	Higher $P_{\text{out}}/T_{\text{out}}$ inside reactor: 15.5 MPa/330 °C	Lower $P_{\text{out}}/T_{\text{out}}$ inside reactor: 9.9 MPa/310 °C
8	Higher $P_{\text{in}}/T_{\text{in}}$ to turbine inlet: 7.72 MPa/292 °C	Lower $P_{\text{in}}/T_{\text{in}}$ to turbine inlet: 4.6 MPa/260 °C
9	Higher thermal efficiency of NPP: up to 37% (38%)	Lower thermal efficiency of NPP: up to 32% (33%)
10	Batch refueling	Refueling on-line
11	Fuel enrichment 3–5%	Fuel – natural UO ₂ (enrichment $\sim 0.7\%$)
12	Wide range of installed capacities from 30 MW _{el} (SMRs) and up to 1660 MW _{el}	Small- and medium-size reactors: 90–880 MW _{el}

ABWRs built and put into operation in Japan. However, nowadays, advanced PWRs of Generation-III⁺ are being built around the world. Major differences between Generation-III⁺ and III are as the following:

- 1) In general, NPPs with Generation-III⁺ reactors have slightly higher thermal efficiencies compared to those of the same type-reactor NPP of Generation-III.
- 2) Generation-III⁺ reactors are equipped with passive-safety systems, which enhance safety.
- 3) Generation-III⁺ reactors are designed for operation of 60 years compared to 30–45 years of Generation-III reactors.

In summary, we would like to stress the major advantages of nuclear power:

- 1) Concentrated and reliable source of almost infinite energy, which is independent of weather conditions (however, it should be noted that within last summers, which were very hot on a record due to fast climate changes, some reactors/NPPs were forced to decrease power load or even were shut down for some time, because of lower levels of water in rivers, etc. and/or of relatively high water temperatures including not only in-land water resources, but, also, sea/ocean waters;

Table 10 Technical and deployment advantages and disadvantages of PHWR-type reactors.

No	
<i>Advantages</i>	
1	Ease of build as does not require large items that can be manufactured by very few heavy industrial plants in the world
2	Mass-flow rates and power shapes can be controlled in individual fuel channels
3	Reactor-coolant flow in pressure channels is interlaced (i.e., in neighboring channels flow has opposite directions), which allowing more uniform axial-density distribution/neutron flux
4	Flexible fuel cycles use natural-uranium plus spent fuel from PWRs and BWRs, and using thorium fuel allow optimum resource use
5	Refueling on-line provides higher capacity factors compared to batch-refueling reactors
6	Extra passive-safety system, as liquid-moderator heat sink, separated from reactor coolant
7	Channel and steam generator replacement/refurbishment allow long plant operation
8	Proven performance in fuel and major components have been demonstrated
9	Inherently modular-core design and SMR design
10	Extensive operating and build experience in multiple countries
<i>Disadvantages</i>	
1	Heavy-water reactor coolant and moderator more expensive than light water and require production facilities
2	Heavy water and natural uranium use gives slightly positive void and power coefficients, necessitating auto-control and two independent and diverse shut-down systems
3	Pressure tubes subjected to creep and sagging, which require their replacement in 20–30 years
4	Non-proliferation issues, because of on-line refueling and potential plutonium diversion, with potential for mixing civilian with overt or covert military uses
5	Limited additional development potential demonstrated to date and no new prototypes
6	No known or existing long-term high-level waste repository despite many years of study
7	Significant new build commitment in India, none in Canada
8	Focus on life extension with limited R&D investment in PHWRs
9	Move towards “fashionable” SMR developments has seemingly bypassed AHWRs

- 2) High capacity factors are achievable, often in excess of 90% with long operating cycles, making units suitable for continuous base-load operation;
- 3) Essentially negligible operating emissions of carbon dioxide (see [Figs. 5 and 6](#)) and relatively small amount of wastes generated (see [Table 12](#)) compared to alternate fossil-fuel thermal power plants plus the nuclear has the lowest death rate per TWh compared to that for other energy sources ([Fig. 7](#));

Fig. 5 Carbon footprint for various energy sources. If Carbon Capture and Storage (CCS) are used then the carbon footprint can be decreased for coal and gas by about 6 fold. (For details on carbon footprint of NPPs – see Fig. 6). Courtesy of Dr. J. Roberts, University of Manchester, UK; based on data from <http://researchbriefings.files.parliament.uk/documents/POST-PN-268/POST-PN-268.pdf>.

- 4) Relatively small amount of fuel required compared to that of fossil-fuel thermal power plants (Table 13); and
- 5) NPPs can supply relatively cheap electricity (see Fig. 8) for re-charging of electrical vehicles during night hours as they usually operate on full load (capacity) 24/7.
- 6) As a result, nuclear power is considered as the most viable source for electricity generation within next 50–100 years. However, nuclear power must operate and compete in energy markets based on relative costs and strategic advantages of the available fuels and energy types.
- 7) In spite of all current advances in nuclear power, NPPs have the following deficiencies: (a) generate radioactive wastes; (b) have relatively low thermal efficiencies, especially, NPPs equipped with light- and heavy-water-cooled reactors (up to 1.6 times lower than that for modern advanced thermal power plants; (c) risk of radiation release during severe accidents; and (d) production of nuclear fuel is not an environment-friendly process. Therefore, all these deficiencies should be addressed in next generation – Generation IV reactors and NPPs.

Conclusions

1. Currently, 33 countries have operating nuclear-power reactors, and 3 countries plan to build nuclear-power reactors. In addition, 30 countries are considering, planning or starting nuclear-power programs, and about 20 countries have expressed their interest in nuclear power. However, 13 countries with NPPs don't plan to build new nuclear-power reactors.
2. In January of 2021, 442 nuclear-power reactors operated around the world, which is less by 2 reactors compared to that before the Fukushima NPP severe accident in March of 2011 (however, the total installed capacity increased by 18 GW_e). This number includes 302 PWRs, 63 BWRs, 49 PHWRs, 14 AGRs, 12 LGRs, and 2 LMFBRs (SFRs). Considering the number of forthcoming reactors, the number of BWRs/ABWRs and PHWRs will decrease within next 20–25 years. Furthermore, within next 10–15 years or so, all AGRs (carbon-dioxide-cooled) and LGRs will be shut down forever.
3. Also, it should be stated that the history of the nuclear-power industry shows that nuclear accidents, especially, severe ones, can override any advantages of various reactors' types, and significantly affect future builds of certain types of reactors, e.g., LGRs or even all types of reactors.
4. Today, based on a summary of various parameters including all pros and cons, PWRs are considered as the most "popular" reactors, which are being built around the world. However, tomorrow and in the future the next generation or Generation-IV reactors/NPPs offering improved performance are planned to be eventually built.
5. In general, the major advantages of nuclear power are: (a) Concentrated and reliable source of almost infinite energy, which is independent of weather conditions; (b) High capacity factors are achievable, often in excess of 90% with long operating cycles, making units suitable for continuous base-load operation; (c) Essentially negligible operating emissions of carbon dioxide and relatively small amount of wastes generated compared to alternate fossil-fuel thermal power plants plus the nuclear has the lowest death rate per TWh compared to that for other energy sources; (d) Relatively small amount of fuel required compared to that of fossil-fuel thermal power plants. As a result, nuclear power is considered as the most viable source for electricity generation within next 50–100 years. However, nuclear power must operate and compete in energy markets based on relative costs and strategic advantages of the available fuels and energy types.
6. In spite of all current advances in nuclear power, NPPs have the following deficiencies: (1) Generate radioactive wastes; (2) Have relatively low thermal efficiencies, especially, NPPs equipped with water-cooled reactors (up to 1.6 times lower than that for modern advanced thermal power plants); (3) Risk of radiation release during severe accidents; and (4) Production of nuclear fuel is not an environment-friendly process. Therefore, all these deficiencies should be addressed in next generation – Generation IV reactors and NPPs.

Glossary

CRF Capital Recovery Factor is the (annual) rate at which capital expenditures financed with debt and equity capital are paid to banks and investors.

D&D Decontamination and Demolition (Decommissioning) is the process by which an operating facility site is returned to its original state before operations. This involves the decontamination of contaminated structures and equipment, the removal of equipment, and the demolition of structures. Under different regulatory regimes this leads to the end (“decommissioning”) of the operating license.

Debt Two forms of debt are (1) a loan from a financial institution and (2) sales of bonds to investors. Both involve repayment of principle and *interest*. Both forms are repaid before payments to equity providers in the case of bankruptcy (which involves the restructuring of assets and liabilities).

Equity At least two forms of equity are (1) funds provided by the owner/operator out of earnings and (2) funds provided by investors hoping for a *rate of return* from profits.

GIF Generation IV International Forum is a group of countries working together to develop advanced reactor technologies, known as “fourth generation” technologies.

IDC Interest During Construction is the amount of financing charges (interest and returns to equity) that accumulate during the construction of a facility.

Interest rate It is the rate of return required by banks or on bonds, see debt.

LC Levelized cost is the value that equates (1) the discounted costs of a facility over its lifetime, including expenditures during construction and decommissioning with (2) the discounted revenues of a facility’s lifetime.

LCOE Levelized cost of electricity is the lifetime levelized cost of a generated megawatt-hour.

Nominal It is the cost or price of a good or service in the year of currency when expended.

PPI Producer Price Index is a measure of inflation relevant to producers, similar to the CPI, the Consumer Price Index, which is a measure of inflation facing consumers.

Real is the nominal cost or price of a good or service inflated or deflated to a currency in a particular year, e.g., 2018.

WACC Weighted Average Cost of Capital is an average of the rate of *interest* on debt investments (e.g., by banks) and the *rate of return* required on equity investments (e.g., by partners) weighted by the percentage of debt and equity to total capitalization (debt + equity). Some authors use WACC as “the cost of money.”

Introduction

Two types of costs, total cost (TC) and levelized cost of electricity (LCOE), provide much of the economic information necessary to determine the competitiveness of nuclear power. Total cost is important because nuclear power plants (NPPs) are capital intensive and required large upfront outlays. Levelized cost is important because it determines whether the NPP can compete in the long run against other generating technologies. The LCOE is a measure of discounted lifetime costs divided by discounted electricity revenues. The LCOE (or simply *LC*; here, the italic font denotes a variable and the roman font denotes a parameter), is that cost that equates the left and right sides of Eq. (1):

$$\sum_t [(I_t + O\&M_t + F_t) \cdot (1 + r)^{-t}] = \sum_t [LC \cdot E_t \cdot (1 + r)^{-t}] \quad (t = -LT, \dots, T) \quad (1)$$

where I_t are investment expenditures (including decommissioning costs) in year t ; $O\&M_t$ are Operations and Maintenance expenditures (including refurbishments) in year t ; F_t are fuel expenditures in year t ; r is the discount rate and $(1 + r)$ is the discount factor, e.g., $(1 + 5\%)$; LC is the levelized electricity (or energy product) generation cost over the plant's lifetime; E_t are the MWh of electricity generated in year t ; LT is the construction lead time; and $LC \cdot E_t$ are electricity revenues in year t , which are discounted to $t = 0$.

Because levelized cost is by definition constant for all years, LC can be taken out of the summation and both sides can be divided by the remainder on the right-hand side. Hence, LC can be defined as in NEA/IEA (2015, p. 28):

$$LC = \sum_t [(I_t + O\&M_t + F_t) \cdot (1 + r)^{-t}] / \sum_t [E_t \cdot (1 + r)^{-t}] \quad (t = -LT, \dots, T). \quad (2)$$

The summations in Eq. (2) run from (1) the start, as defined in IAEA (2019, p. 8), of large construction expenditures when the foundation is poured ($t = -LT$, the construction lead time) to the start of commercial operation ($t = 0$) and (2) from the start of commercial operation to the end of commercial operation, T , the life of the plant. (There is a third period from the end of the commercial life to the end of decommissioning; the cost of which is treated as a capital cost or as a contribution to a sinking fund accounted for in $O\&M$.) LC can be calculated in two ways: (a) using a “top-down” approach by making appropriate simplifying assumptions to Eq. (2) such that each cost is the same in each year of operation, or (b) using a “cash flow” approach by estimating the value of each input in each year on the right-hand side of Eq. (2) and discounting to $t = 0$ (for an example of a cash flow model see Table 3, below). Because of its simplicity and transparency, the first approach is used in this article.

Before discussing each of the inputs in Eq. (2), a distinction should be made between nominal and real values. Nominal costs are those in the currency of the year of the expenditure. Real costs are those in the currency of a specific year (in this article all dollars have been converted to 2018 unless otherwise stated). It is often difficult to tell in the literature whether costs and prices are in nominal currency or in real currency if not explicitly stated. Because taxes are assessed on, and budget outlays are stated in, nominal values, most cost estimates associated with governmental or regulatory oversight are in nominal currency.

Confusion enters when these nominal values are discounted (inflated or deflated) to a particular year. Some estimates use escalation rates. However, escalation rates are associated with particular costs. The escalation rate for fuel would not be the same as the escalation rate for construction materials or labor. Therefore, currency should be discounted using a price index, e.g., a producer price index, and real escalation rates (not including currency inflation) should be applied to those particular costs. Picking the proper escalation rates can be difficult because published versions of these rates generally include inflation and because an assumption is made that a particular input is the same over time, i.e., change orders during construction are not well represented by escalation rates. Further, escalation rates, e.g., for NPP construction, are usually calculated for specific regions. Finally, escalation rates are often calculated by observing changes in final costs; so, some NPP construction cost escalation rates confound real changes in the price of inputs, such as copper or welding labor, with increases in the productivity, availability, reliability, or safety of NPPs.

This article avoids using real escalation rates and discounts US dollars (USD) in each year to USD 2018 using the Producer Price Index for All Commodities (PPIACO) from Federal Reserve Bank (2019). The rate of inflation for producers, such as electric utilities (that use a different set of inputs than consumers for whom food is an important component in calculating the Consumer Price Index, CPI) increased an average of 5.7% per year from 2000 to 2008, then experienced an average of 0% from 2008 to 2018 (the average from 2000 to 2018 was 2.6%). This means that cost estimates for NPP construction, fuel, and $O\&M$ made before July 2008 should be discounted by the PPI, but cost estimates after July 2008 are *similar* to what they would be in 2018, 2019, or 2020 (ignoring real escalation and real changes in the costs of construction, $O\&M$, and fuel). Compare with inflation rates in Rothwell (2021a).

Examples of NPP electricity levelized costs can be found in NEA/IEA (2015). Table 1 updates these calculations. However, the ABWR cost estimate in NEA/IEA (2015) has been replaced with the estimated costs of a System 80+ from ORNL (2011). In each case the investment cost (construction cost plus financing cost) is the largest component of NPP LCOE. Investment costs are lowest in East Asia. The $O\&M$ cost (which is dominated by the cost of labor, see NEA/IEA, 2018a,b) is less than the fuel cost for Chinese

Table 1 LCOE and cost components for nuclear power plants at a 5% discount rate (2018\$).

NPPs and greater than fuel cost for all other NPPs. LCOE is lowest in China and Korea, about the same in the United States, Continental Europe, and Japan, and highest in the UK. (Russia did not participate in writing NEA/IEA (2015), but Hungary provided data on an EU-approved VVER 1200.)

Nuclear Power Plant Construction Costs section discusses the total capital investment costs using the cost estimates for the System 80+, which was based on the System 80 design used at Palo Verde Units 1, 2 and 3, the largest NPP in the United States. This design was eventually purchased by the Korea Electric Power Corporation (KEPCO) and updated to the APR1400, licensed for construction in the United States by the US NRC in August 2019. *Operating and Maintenance Costs* section discusses O&M costs. *Fuel Cycle Costs* section discusses the nuclear fuel cycle and nuclear fuel costs. Finally, *Concluding Remarks* section discusses some caveats regarding Table 1.

Nuclear power plant construction costs

Fig. 1 shows the inputs, systems, and outputs of an NPP (on the history of the development of NPPs, see Maldonado and Brown, 2021). The “systems” correspond to “accounts,” to be discussed below. Here, the two most important metrics are (1) total construction cost and (2) levelized construction cost (GIF/EMWG, 2007, p. 9). This section calculates levelized capital cost, *LKC*, as a function of total capital investment costs, *KC*:

$$LKC = KC\{OC(MW) \cdot [1 + IDC(r, LT)]\} \cdot CRF(r, T)/E \quad (3)$$

where *KC* is total capital investment costs, a function of *OC* and *IDC*; *OC* is overnight cost (including contingency) a function of size, *MW*; *MW* is the size of the plant in net megawatts-electric; *IDC* is the rate of Interest During Construction to finance *KC*, a function of *r* and *LT*; *r* is the appropriate real cost of capital; *LT* is the construction lead time; *T* is the economic life of the facility; *CRF* is the capital recovery factor, a function of *r* and *T*, see Eq. (5); and *E* is the annual electricity output expressed in megawatt-hours (MWh).

Construction cost, *KC*, is the total amount spent on construction and commissioning before any electricity or revenues can be generated (as defined in GIF/EMWG, 2007, p. 79). *KC* is equal to the overnight construction cost with contingency plus financing costs (as measured by *IDC*). To measure these consistently, a set of standard definitions of construction accounts, structures, equipment, and personnel is required. The Code of Accounts (COA) used here is derived from the *Cost Estimating Guidelines for Generation IV Nuclear Energy Systems* (GIF/EMWG, 2007), developed by the Economic Modelling Working Group (EMWG) of the Generation IV International Forum (GIF).

The GIF/EMWG (2007) COA is based on (1) the Energy Economic Database (EEDB) that contains a detailed description of how to calculate the LCOE for nuclear power and fossil-fired electric plants (US DOE, 1988) and on (2) the International Atomic Energy Agency (IAEA) updating the EEDB (IAEA, 2000), giving an international consensus COA that differs from the original EEDB (which is still in common use in the United States).

Fig. 1 Inputs, systems, and outputs of a nuclear power plant. Based on Rothwell GS (2016) *Economics of Nuclear Power*. Routledge Publishers, Francis and Taylor Group. Available from https://www.academia.edu/37151189/The_Economics_of_Future_Nuclear_Power.

One of the primary differences between the EEDB and the IAEA accounting systems is that the latter does not break out labor in the cost accounts. One of the secondary differences is that the IAEA's "Series" are not numbered the same way as is EEDB's "Accounts," particularly for indirect costs. The IAEA numbering system is used in the GIF/EMWG COA. In 2003, the GIF/EMWG began developing a hybrid of the original EEDB and IAEA cost accounting systems; primarily adding back labor, so that labor productivity and wages could be adjusted across GIF member countries. This became the 2007 *Guidelines* (GIF/EMWG, 2007). This article uses the latter to guide the cost estimation of new NPPs.

To calculate total capital investment cost, *KC*, **Table 2** presents the costs for a System 80 + 4-loop (four steam generators) PWR with a net size of 1144 MWe. *KC* includes:

- (1) Account 20, Direct construction costs plus Account 10, which includes pre-construction costs, i.e., those costs before the first concrete is poured for the foundation; in **ORNL (2011)** these costs were included in Account 21.
- (2) Account 30, Indirect costs include engineering and administrative costs that cannot be associated with a specific cost category in Account 20.
- (3) Account 40, Owners' costs include expenses incurred by the owner(s) associated with the plant and plant site, but not including off-site transmission system costs (although some cost estimates include transmission costs in owners' costs, increasing construction costs tremendously); the owners' costs associated with the development of the site, e.g., US NRC and US Environmental Protection Agency (EPA) licensing fees, are set to \$200 million plus 5% of base construction costs plus a contingency of 20%.
- (4) Account 50, Supplemental costs are primarily first fuel core costs (and if first fuel core costs are levelized in the cost of fuel, as is the case here, Account 50 can be set to zero). For heavy water reactors this account includes the cost of heavy water. This account can include D&D costs if these are accounted for as capital costs and not as annual contributions to a sinking fund.
- (5) In **Table 2**, a contingency of 20% is added to direct, indirect, owners', plus any supplemental costs; the appropriate contingency percentage for a "preliminary estimate" is discussed below.
- (6) Account 60, Interest During Construction, *IDC*, expressed as a percentage mark-up on overnight costs, is known as the "IDC factor."

The sum of Accounts 10–50 is the base overnight construction cost, *BASE*. The term "overnight" is used to describe what the construction cost would be if money had no time value. *BASE* plus contingency, *C_{on}*, equals total overnight cost, *OC*. Some references define *OC* without contingency and some references define overnight cost with contingency, as does the US Energy

Table 2 Construction cost estimates for a single unit of a twin PWR in the United States.

<i>System 80+</i>			
<i>COA</i>	<i>General description</i>	<i>Cost in 2018\$ (in millions)</i>	<i>Line</i>
10	Capitalized pre-construction costs (or in Series 21)	\$0	1
21	Structures and improvements	\$639	2
22	Reactor plant equipment	\$856	3
23	Turbine plant equipment	\$632	4
24	Electric plant equipment	\$230	5
25	Heat rejection system	\$138	6
26	Miscellaneous plant equipment	\$132	7
20	Capitalized direct costs	\$2,626	8
30	Capitalized indirect costs	\$1,556	9
40	Capitalized owners cost	\$486	10
50	Capitalized supplemental costs (e.g., first fuel core)	\$0	11
	Base construction costs (<i>BASE</i>)	\$4,668	12
	Contingency (20% of <i>BASE</i>)	\$904	13
	<i>Overnight construction cost</i>	\$5,573	14
	<i>Overnight construction cost/kWe</i>	\$4,871	15
60	Capitalized financing costs (<i>IDC</i>)	\$1,062	16
	<i>Total capital investment cost (KC)</i>	\$6,635	17
	<i>Total capital investment cost/kWe</i>	\$5,800	18
	<i>Annual payment to capital (5% for 60 years)</i>	\$351	19
	<i>Annual generation with 85% capacity factor (GWh)</i>	8,524	20
	<i>Levelized capital cost (LKC)</i>	\$41.12	21

Note: Cost have been increased from **ORNL (2011, pp. 32–33)** with a 2% real annual escalation rate for NPPs not yet under construction. Based on data from ORNL (2011) *Advanced High Temperature Reactor Systems and Economic Analysis*, ORNL/TM-2011/364, prepared by Oak Ridge National Laboratory under the direction of UT-Battelle, Oak Ridge (Table 6). Available from <http://info.ornl.gov/sites/publications/files/Pub32466.pdf>

Information Administration (US EIA, 2020). To make this distinction, *BASE excludes* contingency and *OC includes* contingency. *OC* plus Account 60, *IDC*, equals total capital investment cost, *KC*. To understand the relationship between lead time and compounding *IDC*, see Rothwell (2021a).

Although generally not a part of *KC*, “decontamination and dismantling” (D&D) costs should be set aside before or during operation for plant D&D after operation. In the latter case, D&D funding is treated as a sinking fund (and is assigned to O&M costs, see next section). In some IAEA software programs, the cost of decommissioning is added to the cost of construction, and no return is allowed on these set-aside funds under the implicit assumption that the D&D escalation rate is equal to the rate of return on the decommissioning funds. This greatly increases the total amount to finance by the time of commercial operation and leads to differences in levelized cost when compared to non-IAEA cost estimates.

The total capital investment cost, *KC*, can also be calculated with a cash flow model. *KC* is calculated in Table 3 based on the overnight cost from Table 2. The financing costs are assumed to be paid once in the middle of the year. The *KC* in Table 3 is slightly higher (\$6,644,760) than in Table 2 (\$6,635,000) due to differences in the calculation of *IDC*.

The remainder of this section discusses assumptions made above regarding (1) the appropriate contingency rate, see line 13 in Table 2; (2) the appropriate discount rate, see line 19; and (3) the appropriate capacity factor, see line 20. First, the appropriate contingency rate depends on the level of project definition or estimate “class.” Traditionally, cost contingency estimation relied heavily on expert judgement based on various cost-engineering standards, whereby contingency was added to the cost estimate to provide a reserve for cost risks and uncertainties during construction. OPEC (2018) discusses the typical estimating method for each estimate class: a Class (5) estimate is for screening among alternatives using parametric models, analogy, and/or judgement; a Class (4) estimate is for feasibility using parametric models with specified equipment; a Class (3) estimate is for budget allocation using semi-detailed unit costs for activity level line items; a Class (2) estimate is for establishing a project baseline using detailed unit costs with a general material take-off list (MTOL) with quantities and types; and a Class (1) estimate is for bidding or evaluating a bid using detailed unit costs with a detailed MTOL. Table 4 gives contingencies recommended by the Electric Power Research Institute (EPRI, 1993) by class. A 20% contingency, as in Table 2, is appropriate for a preliminary estimate. (See D’haeseleer, 2013, pp. 73–77, for a discussion of these issues.) Rothwell (2005) shows how to translate standard deviations of the cost estimate (e.g., from a Monte Carlo simulation) into a contingency rate and vice versa. This method can be applied to construction lead time, fuel prices, etc.; see Rothwell (2016).

Table 3 Cash flow calculation of total capital investment cost.

Year	Year to completion	%	KC	KC	KC	KC
		Construction	$r = 10\%$	$r = 7\%$	$r = 5\%$	$r = 3\%$
		Expenditure	M USD	M USD	M USD	M USD
2018	–7	0.00%	\$0.00	\$0.00	\$0.00	\$0.00
2019	–6	14.000%	\$1,449.63	\$1,211.15	\$1,071.36	\$945.47
2020	–5	14.000%	\$1,317.84	\$1,131.92	\$1,020.34	\$917.93
2021	–4	15.000%	\$1,283.61	\$1,133.43	\$1,041.16	\$954.85
2022	–3	15.000%	\$1,166.92	\$1,059.28	\$991.58	\$927.04
2023	–2	14.000%	\$990.12	\$923.98	\$881.41	\$840.03
2024	–1	14.000%	\$900.10	\$863.53	\$839.44	\$815.57
2025	0	14.000%	\$818.28	\$807.04	\$799.46	\$791.81
Totals		100.00%	\$7,926.51	\$7,130.34	\$6,644.76	\$6,192.70

Note: *KC* is the total capital investment cost.

Based on data from Based on data from ORNL (2011) *Advanced High Temperature Reactor Systems and Economic Analysis*, ORNL/TM-2011/364, prepared by Oak Ridge National Laboratory under the direction of UT-Battelle, Oak Ridge (Table 6).

Available from <http://info.ornl.gov/sites/publications/files/Pub32466.pdf>

Table 4 Suggested contingency rates as a function of estimate class.

Estimate	EPRI estimate	EPRI
Class	Designation	Contingency
5	Conceptual	Not available
4	Simplified	30–50%
3	Preliminary	15–30%
2	Detailed	10–20%
1	Finalized	5–10%

Based on EPRI (Electric Power Research Institute) (1993) *Technology Assessment Guide*. Palo Alto, CA, TR-102276-V1R7.

Second, there is the question of the appropriate discount rate. Traditionally, economists have argued that the discount rate should be the real corporate, tax-adjusted weighted average cost of capital (WACC). However, the tax rate varies significantly from one electric utility to another, so is ignored here.

$$r = \text{WACC} = [\mathbf{d} \cdot \text{debt} / (\text{debt} + \text{equity})] + [\mathbf{e} \cdot \text{equity} / (\text{debt} + \text{equity})], \quad (4)$$

where $\mathbf{d}$ is the real rate of return on corporate debt (bond) financing, debt is the total amount of corporate debt (borrowing), equity is the total “stock” financing, and $\mathbf{e}$ is the real rate of return on corporate equity financing. The cost of debt and equity to the nuclear power sector is discussed in Rothwell (2021a).

Focusing on the definition of appropriate long-term cost-benefit evaluations in the US DOE Federal Energy Management Program (US DOE/FEMP, 2017) recommends a discount rate of 2.8% for US government energy projects of 30 years or more, following the Office of Management and Budget guidance. This is approximately equal to economists’ consensus that the “social discount rate” is about 3%. Karoly (2018) presents a literature review of this rate. Hence, fixing the discount rate at 3% real for all expenditures and revenues *after* the electricity generating facility starts selling electricity into the transmission grid is reasonable. This is equivalent to refinancing a construction loan at a lower rate (3%) *after* construction. However, applying a risk premium during construction is also reasonable. For compatibility with NEA/IEA (2010, 2015), the cost of financing during construction are set equal to 3%, 5%, 7%, and 10% for purposes of comparing the costs of electricity generating alternatives; see discussion in NEA (2018). On the other hand, following NEA (2016), the rate of return on decommissioning trust funds can be assumed to be zero, given that cost escalation of decontamination and demolition (D&D) and radioactive waste management are likely to be equal to or greater than the return on these funds (primarily because regulators restrict NPP owner/operators from investing nuclear decommissioning trust funds in low-risk assets).

Also, the NPP owner/operator borrows funds from banks (debt) and uses internal funds and funds from investors (equity) to finance the construction of the plant, where the debt to total liabilities (debt plus equity) ratio can be as high as 80%. Under rate-of-return regulation, amounts of these funds were transparent because of regulatory requirements. In deregulated markets some of these amounts are consider strategic information. To simplify capital accounting, the capital recovery factor (CRF) is the rate at which the NPP owner/operator pays off its debts and pays a return to equity investors. The CRF is a function of r (the WACC in Eq. 4) and the payback period, T (CRF increases with r and decreases with T):

$$\text{CRF} = \left\{ \mathbf{r} \cdot (1 + \mathbf{r})^T / \left[(1 + \mathbf{r})^T - 1 \right] \right\} \quad (5)$$

Third, one must estimate how much electricity is sold in each year. The US NRC (2001) defines several capacity factors, each with a different measure of capacity. In Eqs. (2) and (3), let E be the US NRC’s “net electrical energy generated”; MW is the “net maximum dependable capacity” (dependable capacity is the capacity upon which the transmission grid operator can rely for dispatch); and TT is the total time in a year, i.e., 8766 h (averaging over leap years): $CF \equiv E / (MW \cdot TT)$. Average CFs were less than 78.2% before 1999 (with a minimum average monthly capacity factor of 47% in 1974) and greater than 78.2% after 1998 (with a maximum average monthly capacity factor of 94% in 2018); US EIA (2020).

Operating and maintenance costs

This section discusses non-fuel operations and maintenance (O&M) costs. The GIF/EMWG Guidelines (2007, pp. 97–101) defined the following cost accounts, as well as contingency on estimated O&M costs (these account definitions have been updated to more closely correspond to ORNL, 2011):

- (1) Account 71 On-site staffing expenses includes all management and O&M personnel assigned to the plant site.
- (2) Account 72 Salary related costs: Costs of pensions and benefits, including worker’s compensation insurance, provided for the on-site staff. (These costs can be included in Account 71.)
- (3) Account 73 Consumables includes items such as resins, chemicals, make-up fluids, materials, and other non-depreciable items, such as small equipment and tools required for maintenance. This account also includes the costs of supplies for the spent fuel pool.
- (4) Account 74 Repairs and spare parts: Funds for unanticipated repairs and expenditures on spare parts.
- (5) Account 75 Subcontracted services: Expenditures for personnel not assigned full time to the plant site, e.g., safety reviews, off-site training, environmental monitoring, meteorological surveys, fuel studies, refueling services, other owner home office activities directly supporting the plant, and the costs of external disposal of operational radioactive wastes.
- (6) Account 76 Regulatory fees: In the United States this account includes US NRC annual fees and review costs, as well as other routine safety, environmental, and health physics inspections. In other countries NPP owner/operator annual costs for this category depend on their regulatory environment.
- (7) Account 77 Plant refurbishments and upgrades: Cost of large capital items that must be purchased during operation (e.g., steam generator replacement), averaged over the lifetime of the plant. These expenditures can be estimated as a percentage of construction direct costs.
- (8) Account 78 Taxes and insurance: Property taxes, sales and value-added taxes, and any other non-income-based taxes, as well as premiums for commercial and government liability insurance, property damage insurance, and replacement power insurance.

Table 5 O&M cost estimates for a single unit of a two-unit PWR in the United States.

<i>PWR 4-loop of MWe = 1144</i>			
<i>COA</i>	<i>General description</i>	<i>Cost 2018\$ (millions)</i>	<i>% of annual O&M</i>
71	On-site staffing expenses	\$36.27	22.2%
72	Salary related costs (pensions and benefits)	\$9.68	5.9%
73	Consumables	\$28.72	17.5%
74	Repairs and spare parts	\$7.02	4.3%
75	Subcontracted services	\$9.82	6.0%
76	Regulatory fees	\$6.28	3.8%
77	Capital replacements as 0.5% of direct capital	\$13.13	9.4%
78	Taxes and insurance	\$10.85	6.6%
79	Other general and administrative costs	\$12.27	7.5%
	Contingency (as a percent of total O&M costs)	\$26.81	16.7%
70	<i>Annual O&M Costs</i>	\$160.85	100.0%
	<i>Annual Capital Costs per MWh</i>	\$41.12	
	<i>Annual D&D Costs per MWh</i>	\$2.15	
	<i>Annual O&M Costs per MWh</i>	\$18.87	

Based on ORNL (2011) *Advanced High Temperature Reactor Systems and Economic Analysis*, ORNL/TM-2011/364, prepared by Oak Ridge National Laboratory under the direction of UT-Battelle, Oak Ridge. Available from <http://info.ornl.gov/sites/publications/files/Pub32466.pdf>, updated to 2018\$, with a 2% real annual escalation rate for NPPs not yet under construction.

- (9) Account 79 Other general and administrative costs: Other O&M costs that cannot be accounted for in Accounts 71 through 78, such as office supplies, balance of plant (non-nuclear) O&M, visitors' center, etc.

Table 5 shows O&M cost estimates from [ORNL \(2011, p. 81\)](#). In this estimate annual O&M costs are approximately \$19/MWh. Other discussions of the relationship between staff size and O&M can be found in [Rothwell \(2016, Section 4.3\)](#) and [NEA \(2018, Chapter 2\)](#).

Here refurbishments are estimated at 0.5% of the direct cost of the plant. This provides approximately \$13 million per year, which can be spent every year or accumulated like the D&D fund. There are three categories of refurbishments: uprates, upgrades, and life extensions. Uprates involve increasing the maximum power level at which a commercial NPP is allowed to operate. Upgrades involve the replacement of equipment with (generally) larger or more reliable equipment to allow the production of more electricity or to increase the safety of the NPP. Life extension (also known as "Long Term Operation") can involve uprates and upgrades to operate the plant longer than originally anticipated. See [EPRI \(2013\)](#) and [IAEA \(2018\)](#). In many countries this requires replacing older equipment to bring the plant up to more recent safety standards.

Uprates and upgrades can be found by comparing NPP characteristics from one year to the next in the IAEA's *Nuclear Power Reactors in the World*, e.g., comparing [IAEA \(2019\)](#) to the previous addition. For example, in Sweden after the closure of Barsebäck Units 1 and 2 in 1999, uprates and upgrades at the remaining nine reactors increased their capacity by 1050 MW by the end of 2008 and another 569 MW by mid-2014 ([WNA, 2019](#)). Unfortunately, it is difficult to determine the costs of these uprates and upgrades because announcements regarding future projects are usually in nominal currency and are not broken down in terms of specific equipment or systems.

To this must be added contributions to an Nuclear Decommissioning Trust (NDT, see [NEA 2016](#)) fund such that the value of the fund is equal to the cost of the D&D of the plant, the on-site storage of irradiated nuclear fuel, and the D&D of the nuclear fuel storage facility; see [GIF/EWMG \(2007\)](#) and [McCullum \(2021\)](#). Contributions to an NDT fund, managed by a fiducially distinct entity, are accumulated during operation. The consensus value of D&D is 20% of the Overnight Construction Cost. (This is higher than the 15% assumed in [NEA/IEA, 2015](#)). There is no consensus on the appropriate rate of return on the NDT. Recent experience has shown that real escalation in D&D costs is approximately equal to the rate of return on long-term low-risk investments. See, for example, [CPUC \(2014, pp. 110–129\)](#) and [Southern California Edison \(2016\)](#). Further, without large investments in radioactive waste storage facilities, the cost of waste management could also rise faster than the general rate of inflation (e.g., PPI), eating into the return on D&D funds. Therefore, the annual contribution is assumed to be equal to the estimated decommissioning cost divided by the number of contributing years. Considering the Overnight Cost in **Table 2**, 20% is approximately \$1.1B, divided for 60 years (as assumed in [NEA/IEA, 2015](#)), implies an annual contribution of approximately \$18M or \$2.15/MWh. Finally, the D&D estimates can be very low if it is assumed that the return on NDT funds is equal to the rate investors require on construction expenditures.

Fuel cycle costs

The generic nuclear fuel cycle (**Fig. 2**) consists of (1) uranium mining and milling to create uranium oxide; (2a) conversion from uranium oxide to UF₆ (uranium hexafluoride) and enrichment to increase the percentage of the fissionable U²³⁵ from 0.7% up to

Fig. 2 Generic nuclear fuel cycle (once and twice through). Based on Rothwell GS (2016) *Economics of Nuclear Power*. Routledge Publishers, Francis and Taylor Group. Available from https://www.academia.edu/37151189/The_Economics_of_Future_Nuclear_Power.

5% yielding enriched product and depleted tails, or (2b) fabrication of fuel using natural uranium, such as in Pressurized Heavy Water Reactors; (3) conversion from UF_6 to UO_2 and fabrication into fuel rods and assemblies; (4) irradiation in a nuclear reactor; (5) irradiated fuel storage; (6) reprocessing to separate out (6a) U^{235} and plutonium and the fabrication (6b) of mixed oxide (MOX) fuel by combining recovered U^{235} and plutonium with natural uranium or depleted tails to be reused in a nuclear reactor; and (7) disposal of irradiated fuel and reprocessing residuals into a deep geologic repository (DGR). (On nuclear fuel cycles.) A “once-through” nuclear fuel cycle does not include reprocessing. A “twice-through” nuclear fuel cycle includes one MOX step. A “closed” fuel cycle includes many recycles to burn long-lived isotopes, generally with fast-spectrum nuclear reactors, not discussed in this article; see Heidet (2021).

Most commercial NPPs are Light Water Reactors (LWRs), Pressurized Heavy Water Reactors (PHWRs, including CANDUs (Canada Deuterium, Heavy Water, Uranium reactors), Gas-Cooled Reactors (GCRs), or Light Water Graphite Reactors (LWGRs). Table 6 presents reactor types, NPP types, and a simple description of the fuel they use. Low enriched uranium (LEU) fuel accounting is complex if done precisely reflecting the periods during which each fuel bundle is used in the reactor. Generally, it is assumed that fuel is paid for in a uniform stream over the life of the plant, without regard to the changing isotopic composition of a reactor’s fuel. The isotopic composition of LEU (Low Enriched Uranium), MOX (Mixed Oxide), and CANDU (Canadian Deuterium) natural uranium (NU) fuels is given in Table 7.

One characteristic that distinguishes LEU fuels is their potential burnup, primarily associated with their enrichment (see Fig. 3), defined as the number of megawatt-days, MWd, produced per kgU of fuel (MWd are equal to the number of thermal megawatts, MWth, produced per day times the thermal efficiency, ϵ , of the power plant, yielding MWd.) Consider levelized fuel costs over the life of the NPP and fuel expenditures in each year. Following Rothwell (2016, Section 4.2), the cost per MWh of LEU fuel, F , is

Table 6 Types of nuclear fuel in commercial use (not including fast reactors).

Type	NPP Type	Physical specification
LWR	PWR, VVER BWR, ABWR	Cubic/hexagonal cross-section, 4–5 m long 200–500 kgU per assembly
PHWR	CANDU	10 cm dia. $\times$ 50 cm long, 20 kgU bundle
GCR	Magnox AGR	3 cm dia. $\times$ 1.1 m long slug 24 cm dia. $\times$ 1 m long assembly
LWGR	RBMK	8 cm dia. $\times$ 10 m long assembly

**Fig. 3** Low enriched uranium at 4.5% U-235 product assay. Author calculations based on equations in the text.

$$F = [FC/(\varepsilon \cdot \text{BURN} \cdot 24)] + \text{SNF} \quad (6)$$

where FC is the cost of nuclear fuel in USD per kilogram of uranium (USD/kgU); ε is the thermal efficiency of converting MW-thermal into MW-electric; BURN is the burnup rate measured in thermal megawatt-days per kgU; 24 is the number of thermal MWh in a thermal megawatt-day; and SNF is the interim storage cost of Spent Nuclear Fuel per MWh (assumed to be \$1/MWh real) plus geologic disposal costs (assumed to be \$1/MWh real).

For example, if the burnup rate is 50 megawatt-days per kgU and the efficiency is 33.3%, then the cost of fuel per MWh is the cost of irradiated fuel management and disposal, often assumed to be equal to \$1.33/MWh for management and \$1/MWh for disposal plus the cost of fuel per kgU divided by $[(24 \cdot 50)/3] = 400$. If the cost per kgU is \$2000, then F equals \$5 plus \$2.33, or about \$7.33/MWh. (Fuel prices in Table 1 were estimated in 2014 when both the prices of natural uranium and SWU were higher; see Fig. 4.)

FC in Eq. (6) can be calculated with Eq. (7), in which all prices are given in 2018 USD/kg of product (and ignoring financial charges on expenditures less than one year before using the fuel in an NPP and fractional losses during processing of less than 1%, see Bunn et al., 2003, p. 98):

$$FC = (\text{URAN} \cdot P_{\text{UF6}}) + (\text{SWUS} \cdot P_{\text{SWU}}) + P_{\text{FAB}}, \text{ where} \quad (7)$$

Fig. 4 Natural uranium and SWU spot prices (2019\$/kg). Based on Rothwell GS (2016) *Economics of Nuclear Power*. Routledge Publishers, Francis and Taylor Group. Available from https://www.academia.edu/37151189/The_Economics_of_Future_Nuclear_Power, updated with prices collected semi-annually since 2006 from the UxC LLC website and converted to 2019\$ prices: <https://www.cameco.com/invest/markets/uranium-price>.

$URAN$ is the amount of natural uranium input to produce enriched uranium output; P_{UF_6} is the price of natural uranium plus the conversion of U_3O_8 to UF_6 (e.g., \$10/kgU); $SWUS$ is the number of Separative Work Units required in enrichment, measured in kg; P_{SWU} is the price of enriching uranium hexafluoride, UF_6 ; and P_{FAB} is the price of converting and fabricating UO_2 fuel from enriched UF_6 .

Separative Work Units (SWUs) are a measure of work needed to separate U^{235} from natural uranium; see Rothwell (2009).

In Eq. (8), $URAN$ is the natural uranium input for one kgU of enriched uranium product. As shown in Fig. 3, 20 tU, the approximate amount of 4.5% enriched uranium to generate one gigawatt-year of electricity, requires 188 tonnes of natural uranium and 134,622 SWU, and yields 168 tonnes of depleted uranium with 0.26% U^{235} .

$$URAN = (X_{PE} - X_{TE}) / (X_{FE} - X_{TE}) \quad (8)$$

where X_{FE} is the percentage of U^{235} (assay) in initial natural uranium feed about 0.711%; X_{PE} is the percentage of U^{235} in the enriched uranium product, for example 4.5%; and X_{TE} is the optimal percentage of U^{235} in the tails, e.g., 0.26%.

The optimal tails assay can be approximated by an exponential function of the ratio of P_{SWU} and P_{UF_6} for enrichments with feed assays of 0.711%. Eq. (9) was calculated with ordinary least squares (OLS) with data from numerical optimization with a fixed product assay (here, 4.5%) and is not applicable to other product assays (a similar equation must be estimated for each product assay; X_{TE} is an endogenous variable and without Eq. (9) it must be calculated with an optimization routine). In Eq. (7), $SWUS$ is the number of separative work units required in enrichment, as given in Eq. (10):

$$X_{TE} = \exp \{ -6.085 + 0.468 \cdot [\ln (P_{SWU} / P_{UF_6}) - 0.074 \cdot [\ln (P_{SWU} / P_{UF_6})]^2] \} \quad (9)$$

$$SWUS = [V(X_{PE}) - V(X_{TE})] - URAN \cdot [V(X_{FE}) - V(X_{TE})] \quad (10)$$

$$V(X_i) = (2X_i - 1) \cdot \ln [X_i / (1 - X_i)], \text{ where} \quad (11)$$

where i is either the feed assay, FE , the product assay, PE , or the tail assay, TE , and $V(X_i)$ is known as the "value function," with $0 < X < 1$, i.e., $V(X_{FE})$, $V(X_{PE})$ and $V(X_{TE})$.

Fig. 4 presents spot market uranium and average SWU prices. (Spikes in spot uranium prices were not as pronounced for long-term contract prices; see data at UxC LLC). The period from 1948 to 2020 is divided into (1) Period 1 from 1948 to 1968, before US electric utilities were allowed to own uranium; Period (2) from 1968 to April 1979 when the Three Mile Island accident occurred; Period (3) from the TMI accident to the collapse of the Soviet Union (when the Soviet weapons-grade highly-enriched uranium was dumped on the uranium market); Period (4) from the collapse of the Soviet Union to the Fukushima Dai-ichi accident; and Period (5) from the closure of the Japanese NPPs after the Fukushima accident to early-2020. The peaks and troughs of these series are discussed in Rothwell (2016, pp. 10–12). Using equations from Rothwell (2016, Section 4.3) and assuming the cost of re-conversion and fuel fabrication is \$300/kgU (Rothwell, 2010), LEU fuel prices ranged between about \$1760/kgU in 2007 and 2012 to about \$780/kgU in 2018.

One of the reasons the price of enrichment has been declining is the increasing enrichment capacity in the world market; Table 8. Between 2015 and 2020 the WNA projected that Russian capacity would increase by approximately 2,000,000 SWU and China's capacity would increase by 5,000,000 SWU. Russia and China are attempting to provide increasing capacity for their growing home and international fleets. In the case of China this means that the Chinese NPPs will be using less SWU from the international market. The Chinese will likely continue to increase their indigenous enrichment capacity until they can supply all of their

Table 8 Uranium enrichment capacity (thousands of SWU).

Country	Facility	2010	2015	2020 ^a
France	Orano, Georges Besse I & II	5,500	7,000	7,500
Europe	Urenco: Germany, Netherlands, UK	14,200	14,400	14,900
Japan	JNFL, Rokkasho	75	75	75
USA	Urenco, New Mexico	3,500	4,700	4,700
Russia	Tenex: Angarsk, Novouralsk, Zelenogorsk, Seversk	26,000	26,578	28,660
China	CNNC: Hanzhun & Lanzhou	2,200	5,760	10,700
Other	Various: Argentina, Brazil, India, Pakistan, Iran	75	100	170
	<i>Total SWU/year approximate</i>	51,550	58,600	66,700
	<i>Requirements (WNA reference scenario)</i>	49,154	47,285	57,456
	<i>Difference (surplus)</i>	2,396	11,315	9,244

^aProjection.Based on data in WNA (World Nuclear Association) (2020) *Uranium Enrichment*. Available from <https://www.world-nuclear.org/information-library/nuclear-fuel-cycle/conversion-enrichment-and-fabrication/uranium-enrichment.aspx>.**Fig. 5** Recent world uranium production, 2008–2018. Note: FSU = Former Soviet Union. <https://www.world-nuclear.org/information-library/nuclear-fuel-cycle/mining-of-uranium/world-uranium-mining-production.aspx>

indigenous needs. This increase to supply their own needs is putting downward pressure on the world SWU price. This will put downward price pressure on Orano's plants in France and on Urenco's plants in Germany, the Netherlands, the United Kingdom, and the United States. Because of the inverse tradeoff between enrichment and natural uranium feed, falling prices for SWU should increase the optimal tails assay for uranium product. Thus, the demand for uranium could increase if uranium supply were constant. However, with fewer NPPs operating in Japan, NPPs retiring in Germany, Europe, and the United States, uranium demand is also declining. This could continue until the NPPs under construction come into operation at a rate greater than those retiring. The most recent "Red Book" (NEA/IAEA, 2018b) shows a slight decline in uranium production, see Fig. 5, particularly in the United States where uranium production fell to 735 tons in 2018 (enough to supply about 4 LWRs, see Fig. 3), one-third less than in 2017. As an alternative to enriched uranium fuel, mixed uranium oxide and plutonium oxide fuel (MOX) is available if irradiated nuclear fuel can be reprocessed, see Table 7 and Fig. 6.

Approximate fuel costs, assuming conversion from natural uranium to uranium hexafluoride costs \$10 per pound of uranium feed, uranium hexafluoride and SWU are \$100 per kg, and fuel fabrication is \$300 per kg, for typical burnups and enrichment levels for various NPPs are given in Table 9 with the amounts of natural uranium required for a kgU of LEU and the number of SWU required assuming a tails assay of 0.26% and a product assay of 4.5%. As an alternative to LEU, consider MOX. MOX costs for incumbent MOX producers (those that can produce MOX without new investment) are shown in Fig. 6. (The cost of reprocessing and MOX fuel fabrication is unknown at this time because so little of this type of investment has been done since the delays associated with Rokkasho in Japan and the cancellation of the MOX fuel fabrication facility at the Savannah River Site in South Carolina.) The cost of MOX is higher than any fuel in Table 9. This is primarily because the labor requirements to produce MOX are much higher per tonne of output (measured in Metric Tonnes of Heavy Metal, MTHM) due to radiation safety measures compared to a LEU fuel fabrication facility (Rothwell, 2016, Section A4). ("Minimum Efficient Scale" is that level of output with a cost that is within 10% of the cost of the largest possible facility.)

Fig. 6 The cost of MOX as a function of facility size; MTHM, Metric Tonnes of Heavy Metal. Based on Rothwell GS (2016) *Economics of Nuclear Power*. Routledge Publishers, Francis and Taylor Group. Available from https://www.academia.edu/37151189/The_Economics_of_Future_Nuclear_Power.

Calculations based on Eqs. (6)–(11).

Concluding remarks

Finally, there are some caveats regarding Table 1. China is not a member of the NEA, is an associate member of the IEA, and did not participate in the preparation of NEA/IEA (2015). Cost data was gathered by a consultant under contract to the NEA. Therefore, if China participates in the 2020 survey, these values could change. The Finnish expert submitted cost estimates that mixed values for the EPR under construction and the VVER under consideration. The original table in NEA/IEA (2015, pp. 48–49) included a French “EPR.” However, the experts that submitted these projected cost estimates did so for 2030 and hence were not comparable to projected cost estimates for 2020. The Slovak Republic experts submitted estimates for a “Generation II” LWR (NPP designs that were licensed before 1996), whereas all others submitted estimates for “Generation III” LWRs (NPP designs that were licensed after 1996). For these reasons the cost projections from Finland, France, and the Slovak Republic were not reproduced in Table 1. The Chinese data was included because it was similar to the Korean data.

The cost estimates in this article generally follow the GIF/EMWG (2007): *Cost Estimating Guidelines for Generation IV Nuclear Energy Systems* (where “Generation IV” nuclear power plants are for non-light water reactors under research) and the implementation of these *Guidelines* in ORNL (2011). Where the *Guidelines* did not provide adequate detail, such as in the calculation of fuel costs, calculations following Rothwell (2016) were used. Table 1 summarizes levelized costs for a PWR 4-loop dual unit nuclear power plant (based on the costs of a System 80+) and compares these with the levelized costs of other nuclear power plants for China and OECD member countries. Rothwell (2021b) compares these with other electricity generating technologies.

Glossary

AP1000 Advanced Pressurized reactor (1000 MWe, net) designed by Westinghouse; under construction in the United States, in operation in China.

BTU British Thermal Unit (= 1055 J), MMBTU is one million BTUs.

CRF Capital Recovery Factor is the (annual) rate at which capital expenditures financed with debt and equity capital are paid to banks and investors.

D&D Decontamination and Demolition (Decommissioning) is the process by which an operating facility site is returned to its original state before operations. This involves the decontamination of contaminated structures and equipment, the removal of equipment, and the demolition of structures. Under different regulatory regimes this leads to the end (“decommissioning”) of the operating license.

Debt Two forms of debt are (1) a loan from a financial institution and (2) sales of bonds to investors. Both involve repayment of principle and *interest*. Both forms are repaid before payments to equity providers in the case of bankruptcy (which involves the restructuring of assets and liabilities).

EPR European Pressurized Water Reactor (1650 MWe) designed by Areva/Orano; under construction in Finland, France, and the United Kingdom, in operation in China.

Equity At least two forms of equity are (1) funds provided by the owner/operator out of earnings and (2) funds provided by investors hoping for a *rate of return* from profits.

FOAK First-of-a-Kind technology refers to the set of early (“first”) units over which design and licensing costs can be recovered, justifying the construction of dedicated manufacturing facilities.

GIF Generation IV International Forum is a group of countries working together to develop advanced reactor technologies, known as “fourth generation” technologies.

IDC Interest During Construction is the amount of financing charges (interest and returns to equity) that accumulate during the construction of a facility.

Interest rate The rate of return required by banks or on bonds, see debt.

LC Levelized cost is the value that equates (1) the discounted costs of a facility over its lifetime, including expenditures during construction and decommissioning with (2) the discounted revenues of a facility’s lifetime.

LCOE Levelized cost of electricity is the lifetime levelized cost of a generated megawatt-hour.

Nominal Is the cost or price of a good or service in the year of currency when expended.

Real Is the nominal cost or price of a good or service inflated or deflated to a currency in a particular year.

WACC Weighted Average Cost of Capital is an average of the rate of *interest* on debt investments (e.g., by banks) and the *rate of return* required on equity investments (e.g., by partners) weighted by the percentage of debt and equity to total capitalization (debt + equity). Some authors use WACC as “the cost of money.”

Introduction

The calculation of the Levelized Cost of Electricity (LCOE) is a convenient context in which to examine challenges to the nuclear power industry. See Rothwell (2021a) for more details regarding the economics of nuclear energy. The LCOE is a measure of discounted lifetime costs averaged over discounted lifetime electricity revenues. LCOE can be defined as in NEA/IEA (2015, p. 28):

$$LCOE = \frac{\sum_t [(I_t + O\&M_t + F_t) \cdot (1 + r)^{-t}]}{\sum_t [E_t \cdot (1 + r)^{-t}]} \quad (t = -LT, \dots, T) \quad (1)$$

where I_t are capital investment expenditures (including decommissioning costs) in year t ; $O\&M_t$ are Operations and Maintenance expenditures (including refurbishments) in year t ; F_t is the product of fuel expenditures, F_{MWh} , and E_t in year t ; r is the cost of capital and $(1 + r)$ is the discount factor, e.g., $(1 + 5\%)$; E_t are the MWh of electricity generated in year t ; and LT is the construction lead time.

While there are “non-economic” challenges to nuclear power, such as public acceptance of the siting of nuclear power plants (NPPs) and related facilities, and the misunderstanding of the probability and consequences of NPP accidents, the economic challenges discussed in this chapter are (1) unrealistically high costs of capital imposed by risk-averse private financial markets and (2) the imposition of deregulated electricity markets that do not necessarily compensate the fixed costs of any electricity generation technology. With the introduction of electricity market deregulation and the absence of government support for commercial nuclear power in the European Union (EU), Japan, and the United States, the nuclear power industry in the “West” is giving way to the emergence of nuclear power industries in the “East”: Russia, China, and to some extent, the Republic of Korea.

This can be seen in the levelized cost estimates found in NEA/IEA (2015). Table 1 presents levelized costs for NPPs, where “variable” cost is equal to O&M plus Fuel and Waste costs. (Variable costs must be covered by the price.) The investment cost (construction cost plus financing cost) is the largest component of NPP LCOE. Investment costs are lowest in China and Korea. The O&M cost (which is dominated by the cost of labor, see NEA/IAEA, 2018) is less than the fuel cost for Chinese and Korean NPPs and greater than fuel cost for European and US NPPs. LCOE is lowest in China and Korea, about the same in the United States, Continental Europe, and Japan, and highest in the United Kingdom. (Russia did not participate in NEA/IEA, 2015; however, the NPP in Hungary is an EU-qualified Russian plant).

“The cost of capital to the nuclear sector” section of this chapter discusses problems associated with high costs of capital facing builders of NPPs. “Competition on the transmission grid: Regulated tariffs versus market pricing” section discusses the impact of electricity market liberalization on NPP owner/operators. “Summary of challenges” section discusses the contraction of the nuclear power industry in North America and Western Europe, and the intense competition mounted by the “state capitalist” countries of Russia and China.

The cost of capital to the nuclear sector

Levelized capital cost, LKC, is a function of total capital investment cost and the cost of capital:

$$LKC = KC \{ OC(MW) \cdot [1 + IDC(r, LT)] \} \cdot CRF(r, T) / E \quad (2)$$

where KC is the total capital investment cost, a function of OC (Rothwell, 2021a); OC is overnight cost, including contingency, a function of size, MW ; MW is the size of the plant in net megawatts-electric; IDC is the rate of Interest During Construction to finance KC , a function of r and LT ; r is the appropriate real cost of capital; LT is the construction lead time; T is the economic life of the facility; CRF is the capital recovery factor, a function of r and T , see Eq. (3); and E is the annual electricity output expressed in megawatt-hours (MWh).

The capital recovery factor (CRF) is defined as:

$$CRF = \left\{ r \cdot (1 + r)^T / [(1 + r)^T - 1] \right\} \quad (3)$$

Table 1 LCOE and cost components for nuclear power plants at a 5% discount rate (2018 USD).

Based on data from NEA (Nuclear Energy Agency) (2018a) “Sustainable Development and the Application of Discounting to the Calculation of the Levelised Costs of Electricity,” Nuclear Technology Development and Economics, NEA/NDC/R(2018)1 (June). [http://www.oecd.org/officialdocuments/publicdisplaydocumentpdf/?cote=NEA/NDC/R\(2018\)1&docLanguage=En](http://www.oecd.org/officialdocuments/publicdisplaydocumentpdf/?cote=NEA/NDC/R(2018)1&docLanguage=En), NEA (Nuclear Energy Agency) (2018b) MDEP Annual Report 2018. Paris: OECD. <https://www.oecd-neo.org/mdep/annual-reports/mdep-annual-report-2017.pdf>, updated to 2018.

where T is the payback period on debt, for example, 30 or 40 years, and r is equal to the “debt and equity weighted average discount rate.” The higher the cost of capital and the lower the pay-back period, the higher the CRF. Traditionally, economists (particularly in the United States) have argued that the discount rate, r , should be the real corporate, tax-adjusted weighted average cost of capital (WACC): “The discount rate of 7.86% was used to calculate interest during construction (IDC)...” (MIT, 2018, p. 239). However, the tax rate varies significantly from one electric utility to another, so is ignored here:

$$r = \text{WACC} = [d \cdot \text{debt} / (\text{debt} + \text{equity})] + [e \cdot \text{equity} / (\text{debt} + \text{equity})] \quad (4)$$

where d is the real rate of return on corporate debt (bond) financing, debt is the total amount of corporate debt (borrowing), equity is the total “stock” financing, and e is the real rate of return on corporate equity financing.

In this discussion, a distinction must be made between nominal and real values. Nominal interest rates (and nominal rates of return on equity) are those in the currency of the year of the expenditure. Real interest rates are those in the currency of a specific year. (Interest rates are determined in debt markets; rates of return on equities are determined in “stock” markets.) This chapter uses inflation rates implied by the difference debt markets required to compensate for the risk of inflation.

Further, to understand the relationship between lead time and compounding IDC, consider capital construction expenditures, discounted to the beginning of commercial operation, i.e., when revenues from the project begin to flow:

$$\text{IDC} = \sum_t (\alpha_t \cdot \text{OC}) \cdot [(1 + m)^t - 1], (t = \text{LT}, \dots, 0) \quad (5)$$

where α_t are construction expenditures as a percent of OC in month t ; and m is the monthly cost of capital during construction, $(1 + m) = (1 + r)^{1/12}$.

In addition, the IDC factor, idc , is the percentage add-on to account for financing charges during construction. Because IDC depends on the construction expenditure rate (how much is spent in each month), Eq. (5) can be complicated, because the expenditure rate is not the same over the construction period, with smaller amounts being spent early to excavate the site, larger amounts being spent on equipment in the middle of the project, and smaller amounts being spent at the end on instrumentation, training, and fuel loading. Eq. (5) can be simplified by assuming that the construction expenditures have a uniform distribution, such that $\alpha_t = (1/\text{LT})$, i.e., overnight cost divided by construction lead time, LT, in months. Rothwell (2016, pp. 86-87) shows that idc can be approximated by the following equation:

$$\text{idc} \cong [(m/2) \cdot \text{LT}] + [(m^2/6) \cdot \text{LT}^2] \quad (6)$$

For example, if the construction lead time is 7 years and the annual discount rate is 5%, $\text{idc} = 19\%$. The longer the lead time and the higher the cost of capital, the greater the financing cost, if the lead time is 12 years and the discount rate is 7.86%, $\text{idc} = 59\%$, i.e., over one-half the overnight cost. The construction lead time and the real cost of capital have an enormous influence on the apparent competitiveness of nuclear power in the marketplace of competing electricity generating technologies. The Diablo Canyon NPP required 19 years to complete, the real IDC portion of the KC (known in regulatory accounting as “Allowance for Funds Used During Construction”) was 35%, implying that the real cost of capital was approximately 3.13% (Cox and Gilbert, 1991).

What is the appropriate real cost of capital for evaluating nuclear new build? First, what is the appropriate cost of debt? Many interest rates are tied to the rates on government bonds. The Federal Reserve Bank (the “Fed”) serves as the central bank in the United States. It sells government bonds with different maturities in an open (and international) market to finance government borrowing. The “90-day bond rate” serves as the foundation for other bonds sold by the Fed. In the finance literature this rate is known as the “risk-free” rate under the assumption that the US government will always pay its short-term debts. (During US federal government shutdowns, the risk of non-payment is greater than zero, hence the US government credit rating is not the highest possible.)

The “30-year bond rate” serves as the foundation for rates on 30-year mortgages, as well as infrastructure investments. The Fed sells two types of 30-year bonds: (1) one that yields an annual nominal interest payment and (2) one that yields an annual payment covering changes in the value of the interest payment due to inflation: Treasury Inflation Protected Securities (TIPS). The difference between these rates that buyers are willing to buy bonds is the expected (general) rate of inflation. In Fig. 1 bonds yielding a nominal interest payment varied from the end of 2014 to the beginning of 2020 between 2.1% and 3.3%. Bonds yielding an inflation-adjusted interest payment varied between 0.5% and 1.3%. This implied that the expected (general) annual inflation rate varied between 1.6% and 2.1%, i.e., less than that experienced by US producers from 2000 to 2018, but greater than from 2008 to 2018.

Second, the next issue is determining the appropriate risk premium to add to the “risk-free” rate. Generally, this is a function of an entity’s credit rating. There are many credit-rating services, for example, Standard & Poor’s (SP Global, 2019) and Moody’s Investor Services. Usually, the lower the credit rating, the higher the required yield that must be offered to sell bonds to investors. For example, the highest rated country, Switzerland, has a credit rating of AAA and can sell its bonds at -0.95% , i.e., investors must pay the Swiss government almost 1% to be insured that their principle will be paid back to them. On the other hand, Brazil has the lowest credit rating in Table 2 and must pay investors a return of approximately 7.26%.

Third, to give context to the relationship between Wall Street and the nuclear power industry, in the 1970s, with double-digit inflation and associated increases in the cost of capital of over 20% a year, capital intensive nuclear plants were cancelled. After the accident at Three Mile Island on 28 March 1979, the time taken to license NPPs doubled, leading to even more nuclear plant cancellations. In 1983, the Washington Public Power Supply System defaulted on \$2.25 billion in bonds (\$4.5 billion in 2018 US dollars)—something that Wall Street has neither forgotten nor forgiven. Therefore, Wall Street bond rating agencies have been very risk averse regarding the financing of NPP construction. Regarding the required rate of return on electric utility equity, this is more

Based on NEA (Nuclear Energy Agency) and International Energy Agency (IEA) (2015) *Projected Costs of Generating Electricity, 2015 Update*. Paris: OECD. <https://www.oecd-neo.org/ndd/pubs/2015/7057-proj-costs-electricity-2015.pdf>, updated with data from (1) https://en.wikipedia.org/wiki/List_of_countries_by_credit_rating, (2) <https://tradingeconomics.com/bonds>, (3) <http://www.oecd.org/economy/economic-outlook/>, and (4) <https://www.ceicdata.com/en/indicator/russia/gdp-deflator-growth>.

difficult to determine given the strategic (stock) market implications of such information. A second-hand source (Utility Dive, 2018) announced,

A new report from credit ratings agency Moody's Investor Services paints a generally stable picture of utility holding company finances, though that is heavily dependent on the extent to which revenues are generated by regulated operations... While the “vast majority” of North American investor-owned utility holding companies are rated Baa, the agency concluded Exelon and Public Service Enterprise Group have the highest levels of operating risk due to their generation assets in competitive markets... The firm said Exelon's credit profile is constrained by its higher-risk merchant power subsidiary, Exelon Generation Co., which owns unregulated nuclear generation facilities and a retail energy trading and marketing business.

Therefore, US electric utility debt and equity are considered about as risky as Russian government bonds, which had a *nominal* yield of 7.11% (in August 2019). This is unlikely to be the appropriate *nominal* weighted cost of capital for NPP owner/operators. Fig. 2 shows the relationship between the WACC and the nuclear's LCOE, primarily a function of the levelized capital investment cost in Eq. (2). For example, assuming a WACC of 7.86% leads to a nuclear LCOE of \$107/MWh, much higher than any in Table 1.

The consequences of using such high WACCs are several. First, while WACCs higher than 5% might reflect the risk of building an NPP, they do not reflect the riskiness of producing electricity revenues, unless deregulation has been imposed *after* the NPP has been built, see next section. Second, there is an implicit assumption that sinking funds, for example, for D&D costs and waste management, are earning rates of return equal to the WACC charged in the market for construction. If these costs are increasing at real rates higher than the general inflation rate (due to the increases in regulation and lack of storage sites), there will be less put aside during operation

Fig. 2 Nuclear energy LCOE as a function of the discount rate. Author calculations based on Eq. (2).

Fig. 3 The present value of benefits as a function of the discount rate. Based on NEA (Nuclear Energy Agency) (2018a). “Sustainable Development and the Application of Discounting to the Calculation of the Levelised Costs of Electricity,” Nuclear Technology Development and Economics, NEA/NDC/R(2018)1 (June). [http://www.oecd.org/officialdocuments/publicdisplaydocumentpdf/?cote=NEA/NDC/R\(2018\)1&docLanguage=En](http://www.oecd.org/officialdocuments/publicdisplaydocumentpdf/?cote=NEA/NDC/R(2018)1&docLanguage=En), NEA (Nuclear Energy Agency) (2018b) *MDEP Annual Report 2018*. Paris: OECD. <https://www.oecd-neia.org/mdep/annual-reports/mdep-annual-report-2017.pdf>, Fig. 2.

than will be required. Fig. 3 shows after revenues received 23 years (the approximate length of a human “generation”) at a discount rate of 3%, are only worth half as much as revenues in the present (NEA, 2018a). At a discount rate of 7.86% the present value of revenues after 23 years is only worth 17.5% of revenues generated in the present. For long-life assets, such as NPPs, at discount rates above 7% the value of the assets is next to nothing for the children and grandchildren of the builders of power plants in the present. This contradicts the goal of sustainability. For these reasons, the levelized cost methodology requires different discount rates during different periods in the life cycle of a long-term asset. For example, a more sustainable-oriented approach would use the corporate cost of capital to discount expenses during construction and use the social discount rate to discount revenues (Karoly, 2018) during operation.

Thus, determining the appropriate rate for discounting costs and benefits over multiple lifetimes, such as one finds when evaluating investments in the electricity generation and distribution system, is objectively difficult. Therefore, one of the most difficult economic challenges facing the nuclear power industries in countries with liberal capitalist economies is to find financing for new NPP construction due to its perceived riskiness, particularly the risks associated with building on time and on budget. Many electric utilities in these countries have turned to either (1) their governments for aid, such as loan guarantees (Rothwell, 2016, Chapter 2) or (2) foreign financing.

Competition on the transmission grid: Regulated tariffs versus market pricing

Both “old” and “new” nuclear power compete with “old” and “new” fossil-fired electricity generators, as well as “new” renewable generators (Rothwell, 2021b). Because of greenhouse gas concerns, many countries have adopted policies that encourage the

phasing out of old generators in favor of new generators. For example, old coal plants are being replaced with new CCGTs (Combined Cycle Gas Turbines) that produce half the CO₂ of coal-fired generators and little of the other pollutants that coal burning produces. At the same time, renewables with high capital costs and low capacity factors are being given priority in electricity markets, as well as subsidies, such as tax breaks. This section compares the LCOEs of various electricity generating alternatives. Following the assumptions in [US EIA \(2019\)](#) and in [NEA/IEA \(2015\)](#), [Table 3](#) compares levelized cost of (“Advanced”) CCGT, (“Advanced”) Nuclear, (“On-shore”) Wind, and (“Fixed-tilt”) Solar PV as defined in [US EIA \(2019\)](#), supplemented with assumptions from [US EIA \(2016\)](#) and [NEA/IEA \(2015\)](#), assuming a weighted cost of capital of 5%.

For the United States (only), assumptions in [NEA/IEA \(2015\)](#) are updated using the assumptions in [US EIA \(2019\)](#). The CCGT alternative includes a carbon fee based on \$30.00/tCO₂ and the nuclear alternative includes an irradiated fuel fee of \$2.33/MWh (for storage and disposal). At \$5.50 per MMBTU (\$5.21 per Gigajoule), CCGT is the cheapest alternative. The levelized cost of nuclear and onshore wind are approximately the same. Solar PV is significantly higher due to its low capacity factor. These levelized costs are based on published assumptions and can be updated with updates of the relevant publications. These results depend on the price of natural gas ([Federal Reserve Bank of St. Louis, 2020](#)).

Comparing these results with the calculations in [Tables 1 and 3](#), new nuclear was competitive with natural gas CCGT between 2000 and 2008. (Note: the projected costs of new nuclear in [Table 3](#) are slightly different than in [Table 1](#) due to different assumptions.) However, new nuclear cannot compete with natural gas prices below \$4/MMBTU (\$3.79/Gigajoule) in deregulated markets in the United States: it is unlikely that revenues would cover the fixed costs of NPP construction. See [Table 3](#). Even if there were carbon taxes of \$30/tCO₂, new nuclear would not be competitive outside of China and Korea, see [Table 1](#).

Although most CCGT generators have long-term contracts, the opportunity cost of using their contracted natural gas for electricity generation is the spot price. For this reason, this price is used to convert the price of natural gas into the price of electricity as in [Fig. 4](#). This is used to calculate the “spark spread” ([US EIA \(Energy Information Administration\), 2013](#)): “The spark spread is the difference between the price received by a generator for electricity produced and the cost of the natural gas needed to produce that electricity.” To understand the influence of natural gas prices, [Fig. 5](#) presents “CCGT electricity prices” as a function of the monthly Henry-Hub spot-market prices in Louisiana from 1994 to 2020 in 2018 USD. If existing nuclear variable costs are similar to new nuclear variable costs (i.e., construction costs have been paid off for plants older than 30 years), existing NPPs could be competitive with CCGT with natural gas prices above \$4/MMBTU (\$3.79/Gigajoule). However, with natural gas bouncing between \$2 and \$4/MMBTU (\$1.90 and \$3.79/Gigajoule), it would be difficult to justify investment in upgrades, uprates, or life extensions without the certainty that these investments could be recovered. On the other hand, natural gas prices have generally been twice as high in Europe and three times as high in Japan, see [Knoema \(2019\)](#). Therefore, it is more likely that incremental investments and new nuclear power could be justified in Europe assuming rising natural gas prices and carbon taxes.

Table 3 Levelised cost for four electricity generation technologies, 2018 US\$, $r = 5\%$.

Input		CCGT	Nuclear	Wind	Solar PV
Levelized Capital Cost + D&D	\$/MWh	\$7.45	\$49.57	\$50.48	\$88.74
Levelized O&M Cost	\$/MWh	\$3.44	\$16.24	\$19.73	\$18.30
Levelized Fuel	\$/MWh	\$34.10	\$9.33	\$0.00	\$0.00
Levelized Fuel CO ₂ Fee	\$/MWh	\$9.89	\$0.00	\$0.00	\$0.00
Levelized Cost without waste fee	\$/MWh	\$45.00	\$72.80	\$70.20	\$107.04
Levelized Cost with waste fee	\$/MWh	\$54.89	\$75.13	\$70.20	\$107.04

Based on Rothwell GS (2021b) “Economics of Nuclear Power Versus Other Energy Sources,” Chapter 01305, this Encyclopedia.

Fig. 4 Levelised cost for new natural gas generation, 2018 US\$. Based on data from Rothwell GS (2021b) “Economics of Nuclear Power Versus Other Energy Sources,” Chapter 01305, this Encyclopedia, Table 9.

Fig. 5 Cost of CCGT electricity as a function of the price of natural gas in year, 1994–2020. Calculations based on Fig. 4 with data from Federal Reserve Bank of St. Louis (2020) “Henry Hub Natural Gas Spot Price”. <https://fred.stlouisfed.org/series/DHHNGSP>.

With US states’ experience in deregulating tariffs in many industries and with increasing construction of natural gas CCGTs in the “dash for gas” in the 1990s state legislatures directed public utility commissions to create markets to set prices in the electric power industry. This involved breaking the electric industry into (1) generation, (2) transmission, and (3) distribution sectors. Because strong network economies, transmission was determined to be a “natural monopoly,” and remained under control of the state-regulated utility (Rothwell and Gomez, 2003, p. 75).

Under rate-of-return regulation generation, dispatch was a function of average cost, similar to levelized cost. Under a regulated monopoly, compensating electric utilities based on the load factor of their plant (in particular those not owned by the utility) is equivalent to paying each generator its technology specific (fixed) capacity and (variable) energy costs. This can be observed on the left-hand side of Fig. 6, where three different generation technologies, GN, are dispatched to cover a load duration curve (Oren, 2000). The generator with the highest fixed costs and the lowest variable cost, GN₃ (a base-load generator), receives its fixed, F_3 , and variable costs, C_3 , for producing energy: $[F_3 + C_3 \cdot (T_1 + T_2 + T_3)]$, where $(T_1 + T_2 + T_3)$ is its total generating time. Further, the generator with the lowest fixed cost and the highest variable cost, GN₁ (a peaking generator), receives its fixed and variable costs during the period it is producing energy, $F_1 + (C_1 \cdot T_1)$, where T_1 is its total generating time. In this way generation revenues cover the fixed and variable costs of each technology.

However, in a competitive generation market, in each period electricity generators receive the highest bid in each period, assumed to be equal to the variable cost of the most expensive (highest cost) generator dispatched in that period. On the right-hand side of Fig. 6, hours with higher load factors, the marginal energy cost (market price) is equal to the lowest variable generation cost, C_3 . In hours with lower load factors, the marginal energy cost is equal to the highest variable generation cost, C_1 . Therefore, generators with the highest load factors will receive $(C_1 \cdot T_1 + C_2 \cdot T_2 + C_3 \cdot T_3)$ and generators with the lowest load factors will receive $(C_1 \cdot T_1)$. The sum of the marginal cost times the duration during which it applies $(\sum C_j \cdot T_j)$ is equal to *only* the variable costs of producing electricity, albeit at the bid (variable cost) of the last generator dispatched. Thus, if generators are paid a uniform average variable cost for their energy, they can end up with a shortfall in covering the fixed cost of their technology. This is the reason that some systems have introduced an explicit *capacity payment* (here, equal to F_1) to generators to pay generators’ fixed cost, e.g., in MISO (see below).

In states with deregulated generation, markets were established in which generators would, for example, place day-ahead bids for each period (e.g., each half hour) and the market operator would dispatch the lowest bidder first, the second lowest bidder next, etc., until demand in each period was met. The price in each period was determined by the highest bid. Bids were assumed to be the marginal (average variable) cost of electricity provision (e.g., fuel costs), with capital costs covered under the highest bid. Further, renewables, in most cases, have been given “must-run” status, e.g., whenever the sun is shining, solar generators are dispatched, displacing other bidders. Also, but independently, consumers were given the right to choose their distributor, who, in turn, purchased rights to future electricity for their customers. Given that generation and retail markets were established on a state-by-state basis, the electricity industry in the United States became a complicated patchwork of overlapping jurisdictions, Kulkarni (2016).

The US Federal Energy Regulatory Commission (US FERC, 2020), describes 10 electricity markets in the United States where many south-eastern and western states of the United States are still rate-of-return regulated within the state and compete in interstate markets:

CAISO California Independent System Operator “operates a competitive wholesale electricity market in California and manages the reliability of its transmission grid.”

Fig. 6 Load slice and marginal cost pricing. Based on Oren S (2000) "Capacity Payments and Supply Adequacy in Competitive Electricity Markets," presented at the VII Symposium of Specialists in Electric Operational and Expansion Planning (SEPOPE), May 21–26, Curitiba, Brazil.

ERCOT Electricity Reliability Council of Texas coordinates approximately 90% of Texas' electrical load.

MISO Midcontinent Independent System Operator "operates the transmission system and a centrally dispatched market in portions of 15 states in the Midwest and the South, extending from Michigan and Indiana to Montana and from the Canadian border to" Louisiana and Mississippi.

ISO-NE Independent System Operator-New England "serves six New England states: Connecticut, Maine, Massachusetts, New Hampshire, Rhode Island, and Vermont."

NYISO New York Independent System Operator covers all of the state of New York.

Northwest Is "composed of all or major portions of the states of Washington, Oregon, Idaho, Wyoming, Montana, Nevada, Utah, a small portion of Northern California" and the Canadian provinces of British Columbia and Alberta.

PJM Pennsylvania, New Jersey and Maryland "centrally dispatches generation and coordinates wholesale electricity in all or part of 13 states."

Southeast "Includes all or parts of Florida, Georgia, Alabama, Mississippi, North Carolina, Missouri, and Tennessee."

Southwest "Encompasses the Arizona, New Mexico, southern Nevada, and the Rocky Mountain Power Area."

SPP Southwest Power Pool manages transmission in 14 states.

To further complicate the choice between generation technologies, the cost of natural gas has appeared to be "too cheap to avoid" in North America. Most analysts assume that the price of natural gas will continue to be low (below \$4/MMBTU, \$3.79/Gigajoule) for the foreseeable future. With the market price of electricity driven by natural gas prices, consumers must absorb more of the risk of electricity price spikes because the electric utilities have invested so heavily in CCGT capacity. For example, if natural gas pipelines become congested, the price of electricity can climb above \$1000/MWh. As GTM (2019) stated, "Last week as Texas' ERCOT grid reached its price cap of \$9,000 per megawatt-hour and the price map on ERCOT's website became a solid and deep red, many energy market wonks highlighted that this is a feature, not a failure, of the market."

Because deregulation schemes as implemented in the United Kingdom, the United States, and, to some extent in the EU, favored low capital cost (with high fuel costs) electricity generators, as well as schemes to favor renewables (to some extent to discourage high fossil fuel usage) with must-run status, NPPs are losing market share. As long as there are no payments to capacity and subsidies to renewables, nuclear power faces an almost insurmountable economic challenge in the face of market liberalization while providing the highest share of non-greenhouse gas electricity in many hydro-starved countries with few energy storage

resources. (Future energy storage technologies for nuclear heat could increase the complementarity of nuclear power with non-dispatchable renewables, see [Forsberg, 2021](#)).

Summary of challenges

To conclude there are two primary problems facing the NPP construction and operation industries: (1) extraordinarily high costs of capital on capital intensive NPP projects, and (2) the deregulation of electricity markets that favors fuel intensive generators and “must-run” renewables. Two related issues are (1) overcoming problems associated with maintaining a viable industrial supply chain, allowing the construction of new nuclear on time and on budget, and (2) public perceptions of perceived safety issues after the Fukushima Daiichi accident and the little understood management of radioactive wastes and irradiated fuel. Unless these synergistic issues are resolved the NPP manufacturing industry could end up becoming more concentrated in China and Russia during the remainder of the 21st century where governments are actively supporting NPP construction and the maintenance of a viable nuclear supply chain and actively discouraging dissent over nuclear power policy.

Because of the economies of scale in constructing NPPs, without new orders the nuclear supply chain is disintegrating in the “West.” The cost of constructing new NPPs has increased dramatically since the financial crisis of 2007–08 and the accident at Fukushima Daiichi in 2011, which saw the cancellation of many new orders and the announced closure of NPPs in Germany. With these cancellations and closures came a slowdown in construction of NPPs in the United States (e.g., AP1000) and Europe (e.g., EPR) and the increase in construction costs, leading to more cancellations. While Russia is exporting a dozen VVERs, the cost of construction outside Russia is just below the bids of American and European suppliers and includes up to 80% financing. China hopes to export its Hualong One (HPR1000) NPP, now being constructed in China. Further, Korea has been building the APR1400 in the United Arab Emirates, but is having a difficult time finding Korean government support for building more APR1400s in Korea.

All NPP manufacturers are attempting to market standardized plants, but the regulations in different countries require local amendments to standard designs. The MDEP (Multinational Design Evaluation Programme) is attempting (1) to enhance multi-lateral cooperation within existing regulatory frameworks; (2) to encourage multinational convergence of codes, standards, and safety goals; and (3) to implement the MDEP products to facilitate the licensing of new reactors; [NEA \(2018b\)](#). However, its working groups are focused on the EPR, AP1000, APR1400, VVER, and HPR1000, i.e., no BWR or PHWR NPPs. Should MDEP or a similar body standardize the regulations for LWRs, the supply chains could intertwine, allowing for increased reliance on more international suppliers.

While NPPs are becoming more efficient with increases in capacity factors, the staff size at NPPs is not declining. Because of the high number of staff required to respond to regulatory (e.g., safety) requirements, there are high economies of scale: fewer staff are required per kW with larger plants than with smaller plants ([Rothwell, 2016](#), p. 167, where the minimum staff size of any NPP is estimated to be about 250; also see [NEA/IAEA, 2018](#), p. 31). Compare this to an average staff size at a CCGT of about 3 dozen. [IEEE \(2017\)](#):

On August 1, Michigan-based DTE Energy revealed plans to spend almost \$1 billion to build a 1,100-megawatt gas-fired power plant. When the station enters service in 2022, it will replace three existing coal-fired units that currently employ more than 500 people. Job openings at the new gas-fired plant? Thirty-five full-time employees, says a DTE spokesman.

If NPPs employ 10 times as many people as CCGTs, NPPs might never be competitive with CCGTs as CCGTs become even more automated. Perhaps with integrated PWRs staff sizes will be smaller.

Finally, there appear to be no supply problems with the front-end of the nuclear fuel cycle. Although little uranium is being mined in the United States and there is no endogenous enrichment technology, there are well-functioning markets for both uranium and uranium enrichment services. On the other hand, the public perceives a back-end “waste” problem: the typical 1000 MWe NPP produces about 20 t (see [Rothwell, 2021a](#)) of irradiated nuclear fuel that can be stored in dry casks ([Kessler, 2021](#)). However, the typical CCGT produces 330 kg/MWh, or millions of tonnes of CO₂ per year (as a function of the “carbon intensity factor,” see [US EIA, 2016](#)) with no competitively priced “carbon capture and storage” technology in sight. Therefore, there appears to be a public perception/relations problem that must be overcome for the public to accept nuclear new build. (On other aspects of public opinion, see [Bisconti, 2021](#).)

Glossary

AOO anticipated operational occurrence Events and transients that are expected to occur in a reactor during its operating lifetime (e.g., reactor shutdown, power change, refueling)

Burnup A measure of the amount of fission energy released from a given mass of uranium (heavy metal). Unit is Megawatt-days per kilogram (MWd kg⁻¹), or Gigawatt-days per ton (GWd ton⁻¹). Also referred to as exposure.

BWR Boiling water reactor, a type of light water reactor in which the water moderator in the core is boiling (Hamon, 2021).

CANDU A heavy water power reactor design (Canadian Deuterium-Uranium).

CHF, DO Critical heat flux, dryout. Used to describe the boiling crisis in a BWR fuel assembly.

Cladding The structural material that separates the nuclear fuel from the coolant. In fast reactors it is usually made of steel. In light water reactors it is usually made of an alloy of Zirconium.

Control blade The component used for reactivity control and reactor shutdown in a BWR.

Crud A material that deposits on surfaces exposed to LWR water, becomes radioactive and forms an adherent layer on fuel cladding.

DNB Departure from nucleate boiling. Used to describe the boiling crisis in a PWR fuel assembly.

Fuel assembly A structure containing a group of fuel rods arranged in a regular pattern and supported by other components for operation in the core.

Gen II reactors Refers to reactor designs developed and constructed during the 1970s and 1990s. Many are in their final years of operation.

Gen III reactors Refers to reactor designs developed in the 1990s. A small number have been completed and are operating today.

GDC General design criteria.

GTRF Grid-to-rod fretting. Wear caused by relative motion between the fuel assembly grid and the fuel rod.

HWR Heavy water reactor. This type of reactor uses heavy water as the moderator (Nichita, 2021).

*Retired.

LOCA Loss of coolant accident. This is one of the types of hypothetical accidents that must be considered in the design of a reactor.

LWR Light water reactor. Refers to the class of reactors that use water as the moderator and coolant. PWRs and BWRs belong to this class.

Moderator Substance used to slow neutrons generated by fission for efficient energy transfer.

Neutron flux Number of neutrons crossing a unit area per second. Reaction rates, such as the fission rate, are proportional to the neutron flux.

PCI Pellet-cladding interaction. Refers to several types of interaction between the fuel pellet and the cladding. Interactions include contact, sliding, chemical reaction, etc.

PCMI Pellet-cladding mechanical interaction. Refers specifically to mechanical types of interactions between the fuel pellet and the cladding (e.g., friction, contact, etc.).

PWR Pressurized water reactor. A type of light water reactor that uses pressurized water as the moderator and coolant. The water is maintained below its boiling point. (Brown, 2021).

RCA Reactivity control assembly, generic term for components used to control reactivity.

RCCA Rod cluster control assembly, used for reactivity control and reactor shutdown in a PWR.

Reactivity The extent of the deviation in the core effective multiplication factor (usually denoted as k_{eff}) from its value at a just critical state (at which state $k_{eff} = 1.0$ and the fission rate is constant). A positive (negative) reactivity implies that the ratio of the rate of neutron production to the rate of neutron losses (k_{eff}) is larger (smaller) than 1.0 due to a change in the condition of the core.

SAFDL Specified acceptable design limit. Specified limits have been established by regulation for various calculated conditions in the reactor (see “Fuel assembly and RCA design considerations” in this article).

SCC Stress-corrosion cracking. A material degradation process that involves chemical corrosion processes in conjunction with applied tensile stresses that open small cracks in the material.

USNRC United States Nuclear Regulatory Commission. This is the regulatory body that controls all aspects of nuclear safety in the United States.

Zirconium A transition metal with low neutron absorption, alloys of which have good strength, thermal and corrosion properties in reactor water chemistries.

Introduction

The evolution of modern water reactor nuclear fuel for commercial power production began with the successful design and operation of compact nuclear reactors for submarines, in 1953. Details of the subsequent history of nuclear reactor development are provided in other articles in this encyclopedia (Brown, 2021; Hamon, 2021; Maldonado, 2021). In the United States today, pressurized water reactors (PWR) and boiling water reactors (BWR), both with light water as the moderator, are the primary reactor types. They also operate in several countries worldwide. These are also grouped under the broader category of light water reactor (LWR). Heavy water power reactors (HWR), specifically the CANDU design, are operating in Canada as well as a few other countries. The fuel designs for these three types will be described below.

The theoretical and experimental work underpinning the reactor and fuel designs described here is contained in a large body of published work, of which only a small fraction can be cited here. For general physics, design and operation of power reactors and their fuel, the books by Glasstone and Sesonske (1980) and Olander (2001) are suggested.

Fuel rod, fuel assembly and reactivity control assembly configuration

PWR and BWR

Fuel rod and assembly configurations continued to develop through the 1960s, as a balance was sought between efficient and safe neutron production and utilization (at the simplest level, the ratio of moderator volume to uranium volume) and efficient and safe transfer of nuclear heat to steam production (heat transfer surface area, etc.). For additional details on the nuclear design of a reactor core. Typically, the addition of more, thinner fuel rods in each fuel assembly resulted in more efficient heat transfer and lower temperatures in the fuel. This evolution resulted in a fairly standard configuration appearing in most of Gen II reactor designs. This standard configuration also appears, with some modifications, in the Gen III reactors that have been developed. The detailed descriptions below apply to standard Gen II Westinghouse PWRs, General Electric BWRs, and the CANDU.

A typical PWR or BWR fuel rod is shown in Fig. 1. The fuel rod consists of a zirconium alloy tube (normally referred to as “cladding”) approximately 3.65 m (12 ft) long, with a diameter of about 1 cm, filled with a pressurized inert gas to approximately 1 MPa (150 psia), sealed at each end with end caps or plugs, and containing a stack of pellets, each of which are approximately 1 cm long.

Fig. 1 Typical PWR fuel rod.

The pellets are comprised of slightly enriched (in U^{235}) uranium dioxide, with, in some cases, additional compounds for reactivity control (see “**Neutron absorber materials**” in this article). To allow for some movement of the pellets, their diameter is slightly smaller (a few dozen microns) than the tube inner diameter. The stack is held down by a spring to prevent movement during transportation. It should be noted that the uniform stack of pellets depicted in the figure is an idealization; the pellets will actually be randomly offset, with most pellets touching the cladding at some point. PWR and BWR fuel rods are very similar, except that in a BWR some of the rods may be shorter in length to improve nuclear characteristics. As will be seen, CANDU fuel rods are also similar in design, except that they use natural uranium and are significantly shorter.

Fig. 2 shows the key components of a PWR fuel assembly, with a reactivity control assembly inserted (in PWRs these assemblies are normally called rod cluster control assemblies, or RCCAs). **Fig. 3** shows a top down view of four assemblies. The number of assemblies in a typical PWR core ranges from 121 to 241, depending on the size of the reactor.

The fuel assembly consists of a “skeleton” or “cage” designed to hold the fuel rods in a fixed, typically square lattice (some Russian reactor types employ a hexagonal lattice), as shown in **Fig. 3**. There is no barrier or channel wall between the assemblies; coolant resides in the space between the assemblies. The assemblies shown contain 264 fuel rods in a 17 by 17 square lattice, with the remaining lattice locations taken up by control rod guide tubes or instrument tubes. Other designs exist with different numbers of fuel rods and control rod guide tubes. The assembly structure consists of a number of tubes (guide thimbles) to which grids made of interlocking stamped sheet metal straps are attached (the grid may be welded to the tubes or attached by bulge joints as shown in **Fig. 2**). These grids will hold the fuel rods in place. There are typically six to seven such grids, for a span length of about 55 cm

Fig. 2 Westinghouse PWR fuel assembly.

(22 in.) between grids. In some designs, additional “mixing” grids may be added in the upper spans, to promote additional coolant mixing and heat transfer by inducing lateral momentum to the coolant flow. To accommodate axial growth of the fuel rod due to thermal expansion and radiation effects, as well as ease of manufacture, the support of the fuel rod is usually accomplished by the use of flexible springs attached (or formed by stamping) to the grids.

The tubes serve as guides for the reactivity control assemblies (RCA), as described below. In a Westinghouse design, the center tube serves as a channel for nuclear instrumentation. In other PWR designs, a smaller number of larger tubes and control rods are used.

The tubes are attached to end fittings (or “nozzles”). These provide a means for fixing the assembly in place between the upper and lower core plates of the core, and allowing for lifting and movement during refueling. The top fitting in a PWR includes a set of

Fig. 3 Typical PWR fuel assembly; cross-section view of four assemblies.

leaf springs (shown in the figure; in some PWRs these are coil springs), that are compressed when the top core plate is replaced, to hold the assembly down.

The RCA (also referred to as a rod cluster control assembly, or RCCA in a PWR) for a typical Westinghouse PWR is shown in **Fig. 4**. A number (in a Westinghouse design there are 24) of “rodlets” with length equal to the fuel rods and containing neutron absorbing material (see section “**Neutron absorber materials**”) are attached to a central “spider” which is then attached to a control rod mechanism that keeps the control rods suspended above the fuel assembly during normal operation. The rodlets are lowered into the control rod tubes of the fuel assembly as needed for reactor reactivity control or shutdown, in addition to the chemical shim (borated water for neutron absorption) used in the reactor coolant. The arrangement of control rods varies among PWR designs. Some designs have fewer control rods with larger diameter.

Although there are several differences in geometry and nomenclature between PWRs and BWRs, the basic configuration of the fuel rod and assembly is about the same. **Fig. 5** shows a typical BWR fuel assembly, inserted into its fuel channel.

In a PWR, a single assembly contains typically 200 to 300 fuel rods and tubes that serve as channels through which control rods move. In a BWR, the equivalent component, often called a “bundle,” is a smaller array of typically 100 fuel rods, with grids and end fittings that serve a similar purpose as in a PWR. In addition, there are a smaller number of tubes, and they are designed to allow water flow for neutron moderation, not for control rods. The location and number of these water channels plays an important role in efficient utilization of the fuel; there are a number of configurations being used today. In addition, each fuel assembly is contained within a solid wall fuel channel. A group of four bundles in their respective fuel channels is shown in **Fig. 6**. In a BWR core the number of such fuel assemblies ranges from 240 to 872.

The reactivity control assembly (usually referred to as the control blade assembly) in a BWR consists of a cruciform blade with four wings that moves in the gaps between the fuel channels as shown in **Fig. 6**. The blades, containing absorber material (see section “**Neutron absorber materials**”) are attached to a hub as shown in **Fig. 7**. The hub, or rod, is attached to a drive mechanism at the bottom of the reactor vessel that pushes the blades into the core from below.

HWR (CANDU)

The heavy water reactor known as the CANDU (Canadian Deuterium-Uranium) reactor is described here. Its design is significantly different than an LWR, as outlined below. More details can be found in [Nichita \(2021\)](#).

1. Natural uranium rather than enriched uranium is used as the fuel.
2. The moderator and coolant is heavy water rather than light water.

Fig. 4 Typical Westinghouse PWR control rod cluster (RCCA).

Fig. 5 GE BWR fuel assembly.

Fig. 6 Cross-section of four BWR assemblies with control blade inserted between the channels.

- Whereas in the LWR the same water is used as both moderator and coolant, in a CANDU there are two separate water circuits; one for heavy water at low pressure and temperature to serve primarily as moderator, and one at high pressure used as coolant to transfer the heat generated in the fuel rods to a steam generator.
- The fuel rods and assemblies are arranged horizontally rather than vertically, in individual pressure tubes (instead of pressure vessels in PWR and BWR).
- The pressure tubes can be isolated and accessed individually, so that refueling is performed continuously, while the reactor is at power.

A CANDU fuel bundle is shown in Fig. 8.

From 28 to 37 fuel rods are arranged as shown, attached via the end plugs to an end support plate. The fuel bundle is about 0.5 m long, and is inserted into a horizontal pressure tube of about 10 cm diameter. The pressure tube itself is about 6 m long; a dozen fuel bundles fit inside. Inside the pressure tube, heavy water circulates as coolant and is directed to steam generators. Several hundred of these pressure tubes reside inside a large tank, called a “calandria vessel,” containing cool, low pressure heavy water, as shown in Fig. 9. The pressure tubes are isolated from the moderator by another set of tubes, called “calandria” tubes. Carbon dioxide gas is circulated between the pressure tube and the calandria tube to provide thermal insulation.

Each pressure tube is connected via fittings to individual external piping to circulate the high pressure, high temperature coolant.

The reactivity control assemblies for a CANDU are substantially different than in an LWR. They reside outside of the higher pressure zone, within the calandria vessel, and run vertically among the pressure tubes. They consist of:

- Pipes containing light water, which provide for fine tuning the reactivity and power distributions.
- Stainless steel “adjuster” rods, normally residing in core, and withdrawn when extra reactivity is needed.
- Mechanical control absorbers, tubes of cadmium sandwiched in stainless steel, normally withdrawn, normally used for rapid power control.
- Shutoff rods, with same construction as item 3, used for reactor trip—rapid shutdown.

Similar to the PWR, CANDUs also can use chemical shim to control reactivity (via boron or gadolinium added to the moderator water).

Fig. 7 GE BWR control blade assembly.

Materials of construction

Fuel assembly materials

Modern fuel rod, fuel assembly, and reactivity control structural materials consist primarily of zirconium and nickel alloys, and stainless steel. Because zirconium has a low neutron cross-section in the neutron energy range of interest, nearly all the components within the active core are now constructed of zirconium alloys to minimize neutron loss.

Nickel based alloys, such as Inconel™, are corrosion resistant in the pressure and temperature of reactor environments. This alloy in thin sheet form, is used for example for grids; it retains strength over a wide temperature range. Typically, the top and bottom supporting grids at the ends of the fuel assembly are made of this material, where neutron absorption is not a concern.

Assembly end fittings, control rod clusters and absorber material claddings are typically made of stainless steel.

The materials of construction of fuel and control rod assemblies in a PWR normally consist of:

- (a) Zirconium alloy fuel rod cladding
- (b) Zirconium alloy mid-grids and control rod tubes.
- (c) Nickel based alloy top and bottom grids
- (d) Stainless steel end fittings
- (e) Stainless steel control rod hubs and control rod cladding.

Fig. 8 CANDU fuel bundle.

Fig. 9 Schematic of pressure tube/calandria arrangement.

In a BWR, the materials of construction are typically:

- (a) Zirconium alloy fuel rod cladding
- (b) Zirconium alloy channels and water tubes
- (c) Nickel based alloy grids
- (d) Stainless steel end fittings
- (e) Stainless steel control rod hubs and control rod cladding.

In a CANDU, the pressure tube, fuel cladding, and fuel spacers are all made of zirconium alloy.

Fuel materials

The fuel rod pellet is made of sintered uranium dioxide, UO₂. In LWRs, approximately 96% of the uranium consists of U-238, with the remainder consisting of fissile U-235. The typical pellet is about 1.5 cm long, and about 0.9 cm in diameter.

CANDU fuel consists of 100% natural uranium.

Neutron absorber materials

Neutron absorber materials are used in two ways: for rapid shutdown of the reactor, and for more modest control of the core reactivity to achieve more efficient use of the fuel.

Absorber materials in the control assemblies are typically silver-indium-cadmium (AgInCd) in PWRs, and boron carbide (B_4C) in BWRs (some PWRs also use this material). These compounds are strong neutron absorbers. They are contained as pellets within stainless steel tubes or sandwiched between plates. CANDU reactors typically employ cadmium sandwiched in stainless steel in the form of tubes. When fully inserted into the core, these materials cause a rapid termination of the fission chain reaction.

To improve nuclear performance, PWRs and BWRs also employ absorbers added to the fuel pellets. Gadolinium (in the form of oxide, Gd_2O_3) or Erbium (Er_2O_3) are mixed into some of the fuel pellets, while boron (in the form of ZrB_2) is applied as a coating on the pellets. These materials are weaker neutron absorbers. They are used to reduce the reactivity of the feed assemblies, early in the fuel cycle. As the fuel cycle proceeds, their concentration and, hence, reactivity effect is reduced. They are therefore referred to as “burnable poisons.” In PWRs, these burnable poisons are used to avoid high concentrations of chemical shim in the water early in the cycle. In BWRs, they are used to minimize the amount of control rod maneuvering required for reactivity control through the cycle.

Reactor environment

In order to better understand the key elements of fuel rod and control rod design, it is important first to become familiar with the environment in which these components must operate. The operating environment can be divided into two main areas.

Normal operation

A reactor will spend the vast majority of its operating life in this mode, operating at 100% power, with intermittent shutdowns, primarily for refueling. Many design considerations focus on the ability of the fuel to operate without difficulty, for long periods of time, in this mode.

Tables 1–3 provide a summary of the typical operating conditions for modern PWR, BWR, and CANDU cores.

It can be seen from the tables that the fuel rod components of all three reactor designs are exposed to approximately the same set of environmental conditions, with the exception perhaps of chemistry, which is different among the reactor designs. The materials used and operating environments summarized above lead to physical processes that modify material properties, weaken materials, limit heat transfer, and cause vibration and wear. Any design must be evaluated against all these factors to be successful in-reactor. The discussion will focus primarily on fuel rods and fuel assemblies, where the environment severity is greatest. At the end of each subsection, a discussion of how the environment affects the control rod assembly will be presented.

Table 1 Typical PWR operating conditions.

Parameter	Units	Operation range	Comment
Core pressure	MPa	15.5	Some reactors operate at slightly lower pressure
Heat flux: core average-maximum	(W/cm ²)	55–150	
Thermal neutron flux	Neutrons/cm ² -s	$0-1 \times 10^{14}$	
Core coolant temperature	°C	290–330	Maximum core exit temperature typically 20 °C below the saturation temperature (=346 °C at 15.5 MPa)
Coolant velocity in-core	m/s	5–6	Lithium added to offset boron. Current plants operate at constant pH. Coolant is maintained at high purity, but some small debris, primarily from refueling maintenance activities, is unavoidable.
Coolant chemistry	pH	pH > 7.0	

Table 2 Typical BWR operating conditions.

Parameter	Units	Operation range	Comment
Core pressure	MPa	7.2	Core exit coolant is at saturation temperature with steam quality approximately 15%
Heat flux: core average-maximum	(W/cm ²)	50–110	
Thermal neutron flux	Neutrons/cm ² -s	$0-1 \times 10^{14}$	
Core coolant temperature	°C	215–290	
Coolant velocity in-core	m/s	2–8	Primarily low density steam at core exit
Coolant chemistry	pH	Neutral pH	Contains dissolved oxygen.

Table 3 CANDU operating conditions.

Parameter	Units	Operation range	Comment
Core pressure	MPa	10–11	Larger pressure drop through core than LWRs
Heat flux: core average-maximum	(W/cm ²)	70–130	
Thermal neutron flux	Neutrons/cm ² -s	0–1 × 10 ¹⁴	
Core coolant temperature	°C	265–310	
Coolant velocity in-core	m/s	10–12	
Coolant chemistry	pH	Neutral pH	

Transients and accidents

In the United States, the requirements for the design of LWRs, including their fuel design, are spelled out in the General Design Criteria (GDCs) established by federal regulations (10 CFR 50, Appendix A; “General Design Criteria for Nuclear Power Plants”). There are four specific requirements relating to fuel.

1. The fuel system will not be damaged during any condition of normal operation, including the effects of anticipated operational occurrences (AOOs).
2. Fuel damage during postulated accidents will not be severe enough to prevent control rod insertion when required.
3. The number of fuel rod failures is not underestimated for postulated accidents.
4. Coolability is always maintained.

There are various transients that need to be considered in the design of a nuclear fuel rod, its assembly, and the control rods. These range from transients that may occur on a regular basis, such as reactor shutdown for refueling, to those that occur several times during the reactor’s lifetime, to those that are postulated to occur, but are very unlikely. For moderate frequency transients it is generally required that the fuel survives the transient without damage, so the reactor can be restarted. For postulated accidents it is generally assumed that some fuel damage will occur. As long as long term cooling can be initiated and maintained, this fuel damage is limited and poses little risk to the public. These anticipated transients and more severe events are discussed in detail in (Martin, 2021).

The more frequent transients that may occur, and against which the fuel must be protected, involve (for example) reductions in flow caused by tripping of a main coolant pump, increases in heat local flux caused by inadvertent withdrawal of control rods, and changes in water temperature and/or pressure caused by sudden changes in steam demand. Numerous automatic systems are available and become activated to shut down the reactor and mitigate the changes that are caused by these events. The challenge in safety analysis (see Martin, 2021) is to accurately calculate these conditions, and confirm with a high degree of confidence that fuel damage is avoided.

The impact of these transients on fuel assembly design is summarized in the section “Fuel assembly and RCA design considerations.”

The intense radiation within the core, coupled with high operating temperatures, introduces significant changes in the properties of the materials of construction. These changes must be considered in the design of the components for other aspects such as heat transfer. For this reason, this environmental factor is discussed first. Under normal operating conditions, the environment in the core includes the following:

Reactivity (radiation)

Within the fuel pellet, the fission and radioactive decay processes generate fission gases, causing the pellet to swell and crack. The fission gases may potentially attack the cladding in a process called pellet-cladding interaction (see section “Pellet-cladding interactions”). If the fuel pellet has a boron coating for use as a burnable absorber, helium is also generated, increasing the internal pressure of the fuel rod.

The high neutron flux leads to changes in the basic properties of materials, altering their density and ductility to name a few. In particular, a reduction in density due to the creation of voids in the material means that the mechanical design must accommodate significant growth in some of the components. At the same time, this growth may affect the ability of the material to withstand corrosion.

The effects of radiation are primarily important during normal operation, since their effects require long term exposures. However, large changes in reactivity are possible and must be considered.

Temperature (pressure)

Materials of construction used in reactors (see section “Materials of construction”) are well suited to the high operating temperatures and pressures encountered in a reactor. Where materials are under some stress, however, higher temperature will cause these materials to creep, to relieve the stress. The primary example of this process is the fuel rod cladding, where the high pressure on the outside of the rod will cause the cladding diameter to decrease, until it contacts the fuel pellet. Grids made of zirconium alloy, and to a lesser extent nickel based alloy, will also relax their grip on the fuel rods due to material creep.

It will be seen in “**Conditions within the fuel rod**” that there is a rather large temperature gradient across the fuel pellet. Because the uranium dioxide material is brittle, cracks form shortly after operation begins, changing the pellet diameter.

An additional effect of temperature is to increase the tendency of zirconium alloy materials to pick up hydrogen from the coolant. This tends to reduce the ductility of the metal.

In a PWR, the control rod assemblies are positioned above selected assemblies in the reactor vessel upper plenum, where the average coolant temperature may be moderately higher than the average. In a BWR, they are located below the reactor vessel, in slightly subcooled water.

During several postulated transients, large and rapid changes in heat flux, coolant temperature and pressure may occur. The stresses discussed above may increase significantly in the short term, and fuel rod design must consider these changes.

Water chemistry

Water plays a fundamental role in LWRs and HWRs as a moderator and heat transfer medium. As it transports heat from the reactor core, irradiated materials are also carried to other areas of the reactor. All reactor materials exposed to water react with it to form corrosion products. An early treatise on the issues related to water chemistry in reactors was provided in [Cohen, 1969](#), with significant advances in understanding since then.

Fuel thermal-hydraulics

Fuel thermal-hydraulics normally refer to the environment adjacent to the fuel cladding-water interface. The following paragraphs describe the heat transfer conditions within a fuel assembly during normal and transient operation in summary form to highlight the key elements.

The fluid conditions within the assembly surrounding the fuel rods is adequately described by the simplified one dimensional picture shown in [Fig. 10](#).

In the BWR, the heat generated in the fuel rod is transferred to the water, which then heats up as it flows through the channel. Many additional factors exist to complicate this picture in the actual fuel channel, but the essential features are here. Near the bottom of the channel, heat is transferred through forced convection heat transfer, and consideration is given to sub-cooled boiling. As the water approaches the boiling point, bubbles begin to form on the tube surface, and both the water and tube temperatures become constant, slightly above the saturation temperature of the water. This is the result of a much more efficient form of heat transfer imparted by the vaporization process. This situation persists for some distance, while the steam content in the water becomes greater.

The water-steam mixture goes through several “flow regimes,” as shown the figure. The high pressures and temperatures in PWR and BWR fuel prevent direct observation of these flow regimes. These regimes have been observed in air-water experiments at low pressure, as well as experiments using Freon, which has a low boiling point and scales reasonably well to water. Supporting evidence at reactor conditions has been obtained by measuring the steam fraction through the use of gamma densitometers in the test facility.

At some point the mixture is so dominated by steam that the tube wall becomes dry. This condition is termed “dryout” (DO). At this point, since the heat that must be transferred remains constant in time, the tube temperature suddenly increases. This is the boiling crisis point, and is gauged through the critical power ratio, which is the ratio of power at which this boiling crisis occurs to the operating power of the fuel assembly in core. Limits are placed on the critical power ratio to prevent boiling crisis from occurring during an AOO.

The situation for a PWR in normal operation is similar, except that the heat transfer regimes are limited to those near the bottom of the channel shown in the figure. The incoming water is much colder relative to the temperature at which the water begins to boil, so most of the fuel length is in forced convection. Near the top of the hottest channels, however, subcooled nucleate boiling begins. Bubbles are created at the surface, grow for some period of time, then detach and condense quickly after entering the main stream. If this boiling and bubble generation are intense enough, the bubbles generated cannot escape or condense rapidly enough and a vapor film is formed on the surface. This is the boiling crisis for the PWR, typically called “departure from nucleate boiling” (DNB).

Both DNB and dryout are also referred to as “critical heat flux” (CHF) in the literature.

The detailed heat transfer processes occurring in light and heavy water reactors (including the steam generators) has been well documented in many papers and texts, such as [Collier and Thome \(1994\)](#). The fundamentals of two-phase flow have also been well documented, as in [Wallis \(1969\)](#) and [Lahey and Moody \(1996\)](#).

Conditions within the fuel rod

In a nuclear fuel rod the power generation rate is independent of conditions at the surface of the cladding. Temperatures within the fuel rod and in the cladding will almost instantly respond to changes in the surface heat transfer coefficient, even when nuclear fission is rapidly being shut down. Temperatures in the interior of the fuel rod respond as needed to maintain transfer of the power generated. [Fig. 11](#) shows a typical temperature distribution during normal operation. In the figure, the center of the fuel is at radial position 0, the pellet-inner cladding gap is at approximately 0.9, and the cladding surface is at 1. Because of the relatively low thermal conductivity of the fuel pellet, the centerline temperature is quite high. The temperature drops sharply across the gap filled gap.

Fig. 10 Fluid conditions within a fuel assembly.

As the fuel cycle proceeds, the pellet tends to expand and crack as it responds to the high temperatures and radiation, as previously noted. The high temperature and high coolant pressure cause the cladding to shrink, or "creep down" until it contacts the pellet. The typical condition of the fuel rod after several months of operation is also shown in Fig. 11.

In a transient, rapid changes in local fluid conditions occur within the fuel channel. For example, a reduction in flow due to failure of a pump will lower the axial location at which the coolant becomes saturated and significant additional steam formation begins. In a PWR, the boundary between subcooled forced convection and subcooled nucleate boiling rapidly moves downward in

Fig. 11 Typical fuel and cladding temperature under PWR operating conditions, beginning and end of cycle.

the core (see Fig. 10). The potential for DNB or dryout rapidly increases. At the same time, the heat flux into the channel is rapidly diminishing as control rods are inserted and power is reduced. The challenge in safety analysis is to accurately predict these competing conditions, and confirm with a high degree of confidence that fuel damage, DNB or dryout are avoided.

Conditions on the fuel rod surface

As shown in Fig. 11, the cladding surface temperature (at relative radial position 1) under normal operating conditions is a few degrees above the saturation temperature of water. For a PWR operating at 15.5 MPa (2250 psi), this temperature is approximately 350 °C (662 °F) in the upper region of the core where nucleate boiling is occurring, and for a BWR operating at 7.3 MPa (1050 psi), it is approximately 290 °C (554 °F). These temperatures are well within the normal operating capability of the zirconium alloys in use today. However, the conditions at the surface may result in a more severe chemical environment, as explained below.

In the subcooled nucleate boiling region, shown in Fig. 10, there is a tendency for dissolved or particulate materials carried in the coolant to concentrate at the cladding surface. This process, commonly called “fouling,” occurs on virtually all industrial heat transfer surfaces. The concentrated materials collect as “crud.” This process is illustrated schematically in Fig. 12. With thick crud deposits, solid boron compounds may form, affecting core reactivity. Such events are avoided by careful control of plant chemistry and minimization of corrosion. Crud deposits removed from PWR fuel rods have been examined in detail to understand their structure and chemistry (Byers and Deshon, 2004).

These crud deposits have presented a significant environmental challenge recently, as power densities have increased. In PWRs, boron (dissolved in the water for long-term reactivity control) concentrating within the deposits has resulted in unanticipated changes in core reactivity (PWR Axial Offset Anomaly (AOA), 2004). In both PWRs and BWRs locally thick crud deposits have led to increased cladding temperatures and isolated fuel leaks.

Fig. 12 Schematic of the corrosion product accumulation process on a surface with subcooled nucleate boiling.

Flow induced vibrations

The interaction of the fuel assembly with the coolant and with contacting or nearby structures is a third major environmental challenge. In the relatively high velocity fluid environment several vibration and wear mechanisms come into play. In addition, operations such as shipping and handling of a fuel assembly, and transients the reactor may experience, impose stresses that must be considered in the design. These types of interactions are summarized in Fig. 13. Additional details may be found in Au-Yang (2001) and Pettigrew et al. (1998).

Fluid flow induced vibration occurs in both PWR and BWR fuel assemblies. The vibration in PWRs is more problematic for two reasons:

- PWR fuel assemblies typically use grids made of zirconium alloys, which tend to relax and lose their grip on the rods, as discussed below. BWR fuel assemblies use nickel based alloy grids that do not relax as much, and prevent gaps from forming between the rod and grid support.
- Crossflow across the fuel assembly, which exists in a PWR core and increases the potential for vibration, is prevented in BWRs by the fuel bundle channels.

In a PWR, the control assembly rodlets, when in their normal retracted positions, are located within control rod guide tubes in the reactor vessel upper plenum. The guide tubes contain support structures at several intervals, to guide the rodlets. At the lower end of the guide tube, the axial core flow must turn as it enters the upper plenum and hot leg piping. The rodlets are therefore subject to crossflow and potential vibration effects.

BWR control assemblies move in between the fuel channels as shown in Fig. 7, are not exposed to high crossflows, and are not subject to significant flow induced vibrations.

Pellet-cladding interactions

In the first cycle, the pressure inside the fuel rod is significantly less than the RCS pressure. As shown in Fig. 1, a gap exists initially between the pellet and the cladding, so the fuel rod cladding is in a compressive state during most of the first cycle.

During initial power ascension, the fuel pellet develops small cracks due to its brittle nature. Over two or three cycles of operation (a typical cycle lasts between 12 and 24 months, depending on the reactor type and the core configuration), fission gases formed within the pellet will escape through these cracks into the volume within the cladding, increasing the internal pressure of the fuel rod. At the same time, the cladding strains, or creeps inward in response to the high pressure and temperature of the coolant. Typically, near the end of the first cycle or shortly after the start of the second cycle, hard contact occurs between the pellet and cladding. After hard contact, continued pellet swelling causes the cladding to strain outward, and cladding stresses go from compression to tension.

The changes in the fuel and cladding that occur over the operating life of a fuel assembly are a complex interaction involving nuclear, chemical, heat transfer and material physics that can only be handled accurately with advanced computer models. Fuel suppliers typically use their own proprietary computer codes, focused on their specific fuel design features. These codes require technical review and approval by the United States Nuclear Regulatory Commission (USNRC), as well as other international regulatory agencies. The NRC employs a computer code called FRAPCON (Geelhood et al., 2015) to perform check calculations.

Much design effort has been expended to improve margins to PCI failure. One mitigating feature is to add an inner liner of pure zirconium to the cladding. This softer material is better able to accommodate local stresses. Additives to the fuel pellet achieve the same purpose. Emphasis is also placed on assuring that pellet flaws (typically missing pellet sections cause by chipping during the manufacturing process) are eliminated.

The fuel rod must be capable of withstanding stresses from a number of anticipated transients. These transients may result in sudden increases or decreases in RCS pressure, or increases in local power due to unexpected reactivity insertions. As a result, the pellet may expand or the cladding may experience increased stresses. Verification of the ability of the fuel rod to withstand significant power transients has been performed in test reactors (typically research facilities). In these tests, fuel rod segments are inserted

Fig. 13 Potential interaction sources within the core.

and subjected to sudden power transients to assess their ability to withstand changes in temperature without failure, and to determine failure limits. The design criteria that must be considered are discussed in the next section.

Fuel rod-debris interactions

Small pieces of debris are always present in small quantities in the coolant, typically left behind by maintenance operations during refueling or plant modifications. These may be caught on the grids, and may vibrate against the fuel rod cladding, causing wear and potential cladding failure. This is an important source of potential damage for both PWR and BWR designs, and is typically mitigated by debris filters attached to the fuel assemblies.

Fuel assembly and RCA design considerations

The previous sections described the different environments, both steady state and transient, that could be experienced by fuel rods and control rods, and that pose a challenge to the successful operation of these components.

The geometrical and material configurations described above have remained basically unchanged since the 1970s, having been designed to accommodate the competing mechanical, thermal-hydraulic and, of course, nuclear design constraints and optimization goals. What has driven design since then has been the desire to make greater use of the available energy in the nuclear fuel, primarily by increased power density and increased burnup, while maintaining safety. The total amount of fissile uranium (enrichment) in the fuel assembly drives the ability to support the length of the operating fuel cycle at the reload batch size. The reactivity of the assembly is governed by both the amount of fissile material and the amount of moderator (coolant) within the assembly. This ratio obviously changes throughout the life of the assembly as the fissile material is consumed. The amount of assembly enrichment (and in BWRs, the axial distribution of the enrichment) is chosen to meet both the energy requirements, but also to meet the requirements for the ability of the reactor to meet shutdown reactivity requirements at all points during the cycle.

While each specific fuel design has a fuel rod pitch-to-diameter ratio that gives the optimum moderation point (Tsvetkov, 2021) for reactivity (k -infinity), this ratio is dependent on fuel fissile content and thus exposure as the fuel material depletes in U^{235} and increases Pu^{239} . K -infinity of the lattice is also dependent on the geometry. Increasing the diameter for a given pitch-to-diameter ratio, increases the reactivity, but this also changes the amount of moderation from the interstitial water between fuel rods. These factors are all balanced in the fuel assembly, which is designed to be operated within the core constraints, requiring that, at operating conditions, the temperature or void reactivity be negative. This is affected by both fuel design characteristics and also the core design.

Beyond this, the arrangement of nuclear material within the fuel assembly is driven primarily by limitations on the fuel rod thermal limits, linear heat generation rate and the dryout performance. Water incorporated in non-fuel components of the assembly, such as in control rod and instrumentation thimbles in PWRs and the intra-assembly gaps in BWRs (and so-called water rods) generally increase the power produced in nearby fuel rods. These water containing components also act as neutron traps in the cold, shutdown condition. So both thermal limits and shutdown margin must account for the effect of these features.

Pin-wise power distribution across the fuel assembly is also affected by the presence of burnable absorbers mentioned earlier. While these are primarily used to control reactivity, they have an effect on neighboring fuel rods. As with any feature, this effect can either be an obstacle or a design feature, as it is in BWRs which tailor the lattice power distribution using the burnable absorber.

After several decades of design evolution, the increased use of intermittent power sources such as solar have pushed reactors to move away from constant baseload power, to frequent changes in power during a fuel cycle (see Young, 2021), as well as challenges for large steps in fuel cycle cost performance. This has resulted in additional changes in fuel design focused on:

- (a) Reductions in fuel rod diameter and increases in number of fuel rods to improve nuclear performance. In BWR's there may also be variations in fuel rod length in some portions of the bundle to improve the balance between thermal-hydraulic and fuel rod performance.
- (b) Modifications to the grids to promote heat transfer, in order to accommodate higher power density.
- (c) Improved fuel pellets to accommodate higher power density, more rapid power changes, and higher burnup.
- (d) Improved alloys to reduce corrosion and allow for higher burnup.
- (e) Various improvements to reduce manufacturing costs and increase reliability.

Additionally, the criteria established for fuel performance under normal and accident conditions are being examined for more precise, and potentially beneficial, handling of the fuel response under those conditions. A detailed description of the accidents and transients that must be considered in the design of LWRs and HWRs in the United States is provided in Martin (2021). From the regulatory requirements and guidance provided, Specified Acceptable Design Limits (SAFDLs) for all known damage mechanisms (see "Reactor environment") have been developed over time that form the basis for acceptance of a fuel assembly design. Typical SAFDLs for the fuel rod, fuel assembly, and reactivity control assembly are shown in Table 4.

Table 4 Selected design limits for PWR and BWR fuel assemblies and reactivity control assemblies.

<i>Component</i>	<i>Condition to be avoided</i>	<i>Design limits (SAFDLs)</i>	<i>Comments</i>	<i>Failure(s) prevented</i>
Fuel pellet	Fuel melting	Fuel centerline temperature < melting point		Fuel melting
Cladding	Excessive oxidation	Maximum total oxidation at end-of-life < specified limit		Cladding failure
Cladding	Excessive stress and strain	Rod internal pressure < system pressure	Due to fission gas release	Cladding failure
Cladding	Excessive stress	Clad stress < yield strength	Transients in which the fuel pellet expands against the cladding	Cladding failure
Cladding	Excessive fatigue	The cumulative strain fatigue cycles are less than the design strain fatigue life.	Consider anticipated number of cycles during component life, plus safety factors	Cladding failure
Fuel pellet	Excessive burnup	Discharge burnup < limit established for the fuel		Operation in unverified operational space
Fuel rod	Excessive local power	Peak linear heat generation rate < allowed by tech specs at each axial position	Must consider effect on local power of manufacturing variations, measurement uncertainties, fuel densification, rod to rod gap reduction, etc.	DNB, fuel centerline melt, fuel damage
Fuel rod	DNB/DO	For all transients, ratio of DNB, DO heat flux to maximum local heat flux > 1.0 with 95% probability, 95% confidence		Fuel melting, cladding failure
Fuel rod	Excessive growth	Axial growth < available clearances between top and bottom nozzle		Fuel rod bow, assembly distortion (PWR only)
Fuel assembly grids (PWR)	Excessive oxidation or hydrogen pickup	Grid hydrogen pickup < specified limit		Fuel coolability, incomplete RCCA insertion
Fuel assembly grids	Excessive impact loads during shipping, handling, accidents	Impact load during earthquake < grid damage load established by testing	Accidents up to and including LBLOCA + design basis earthquake	Fuel coolability, incomplete control rod insertion
Fuel assembly end fittings	Excessive impact loads during shipping, handling, accidents	Maximum stress < maximum allowable with safety factor	Accidents up to and including LBLOCA + design basis earthquake	Incomplete control rod insertion
Control rods	Excessive stresses	Stresses in control rod components < yield during shipping and reactor trip	ASME Section III limits and procedures generally used	Incomplete RCCA insertion
Control rods	Excessive resistance to insertion	Control rod insertion time < maximum allowable value	Absorber swelling < limit	Incomplete control rod insertion
BWR channel box	Excessive distortion	Differential irradiation growth, differential hydrogen pickup	Assembly bow < limit	Incomplete control blade insertion
Core	Excessive reactivity insertion	Maximum reactivity change rate < specified limit	Channel distortion < limit accounting for seismic/LOCA loads	DNB, fuel damage
			Interaction of boron dilution or flow change and control rod withdrawal

Glossary

Criticality The normal operating condition of a reactor, in which nuclear fuel sustains a fission chain reaction. A reactor achieves criticality (and is said to be critical) when each fission event releases a sufficient number of neutrons to sustain an ongoing series of reactions.

Fuel burnup The amount of energy released per mass of fuel

Heat flux Heat flow rate (energy per time) per unit area of heated surface

Heat rate Heat flow rate (energy per time)

Power density Heat rate per unit volume (energy per time per volume)

Quality Ratio of the mass flow rate of the gas to the mass flow rate of the gas-liquid mixture.

Reactivity A term expressing the departure of a reactor system from criticality. A positive reactivity addition indicates a move toward supercriticality (power increase). A negative reactivity addition indicates a move toward subcriticality (power decrease).

Abbreviations

ADS	Automatic depressurization system
BWR	Boiling water reactor
ECCS	Emergency core cooling system
ESBWR	Economic simplified boiling water reactor
ESF	Engineered safety feature
GDCS	Gravity-driven cooling system
HPCI	High-pressure coolant injection
HPCS	High-pressure core spray
HPSI	High pressure safety injection
IRWST	In-containment refueling water storage tank
LOCA	Loss of coolant accident
LPCS	Low-pressure core spray
LPSI	Low pressure safety injection
NSSS	Nuclear steam supply system
PCCS	Passive containment cooling system (for the ESBWR)
PCS	Passive containment cooling system (for the AP1000)
PWR	Pressurized water reactor
RCIC	Reactor core isolation cooling (system)
RCS	Reactor coolant system
RHR	Residual heat removal (system)
RPV	Reactor pressure vessel
RWST	Refueling water storage tank
SIT	Safety injection tank
US NRC	United States Nuclear Regulatory Commission

Introduction

The purposes of heat transfer systems in nuclear reactors are two-fold:

- To produce useful energy resulting from the nuclear fission reaction and
- To maintain the reactor systems, structures and components in a safe state, thereby preventing release of radioactivity and protecting the public's health and safety.

To produce useful energy from the fission of nuclear fuel, heat undergoes a number of conversions to other forms of energy, along with being transported from the fuel to the location of final conversion. The final use can be as electricity, as high-temperature heat to drive a chemical reaction such as hydrogen production, or as lower-temperature process heat for industrial applications. The heat transfer systems are designed to enable the energy conversion and transport.

The latter function, maintaining nuclear safety, is ensured by adherence to the nuclear safety goals published by the US Nuclear Regulatory Commission ([US NRC, 1986](#)). Qualitative and quantitative goals were established to limit the risk to individual members of the public and to society from nuclear power plant operation. Adequate heat removal from the nuclear fuel by the heat transfer systems prevents fuel failure and subsequent release of radioactive fission products, and thereby, fulfills the nuclear safety goals. Adequate heat removal is achieved by providing core cooling at a rate sufficient to remove heat generated by nuclear fission, decay heat released by radioactive decay heat of unstable nuclei and heat release associated with system cooldown. Following termination of the fission reaction by control mechanisms, decay heat is the largest heat source that needs to be accommodated.

Energy transport and conversion within reactor heat transfer systems

The energy conversion processes and heat transport in power reactors are summarized in this section. The energy flow and conversion processes for water-cooled power reactors are identified in [Fig. 1](#). The primary source of energy is a nuclear fission reaction in the fuel. A fission reaction produces radioactive fission products that deposit all of their energy as frictional heat in the nuclear fuel elements (in addition to most of their radioactive decay energy). This heat conducts radially outward through the fuel, through the

Fig. 1 Energy flow in water-cooled power systems.

gas gap or contact interface between the fuel pellet and the clad inner surface, and finally through the clad to the surrounding coolant (Young, 2021).

For a direct-cycle water-cooled reactor (e.g. BWR), the coolant water removes heat from the clad outer surface by forced convection and boiling. Coolant water evaporates within the core region, producing steam which carries its thermal energy to the steam turbines. For an indirect cycle water-cooled reactor (e.g. PWR), the coolant water removes heat from the clad outer surface by forced convection and carries its thermal energy to an external steam generator. Secondary-side feedwater to the steam generator removes heat from the outer surface of the steam generator tubes by forced convection and boiling. The secondary-side coolant evaporates within the steam generator, producing steam which carries its thermal energy to the steam turbines.

The thermal energy imparted by the steam on the turbine blades provides the motive force for turbine shaft rotation. The thermal energy of the steam is, in this way, converted to kinetic (i.e. mechanical) energy of the turbine. The turbine powers a generator which produces the end product, energy in the form of electricity.

The steam exhausted from the turbine carries energy which is not used in the Rankine cycle to produce work output. This lower-enthalpy steam is condensed in the main condensers and the resulting condensate is returned to the secondary side of the steam generators in a Pressurized Water Reactor (PWR) or to the Boiling Water Reactor (BWR) feedwater inlet.

The radial temperature distribution in PWR fuel is illustrated in Fig. 2. The classical heat conduction equation is solved to obtain the temperature distribution as a function of space and time within the fuel pellet.

$$\rho c_p \frac{\partial T}{\partial t} = \nabla k \nabla T + q''' [\text{kW m}^{-3}] \quad (1)$$

Fig. 2 Radial temperature distribution for a PWR fuel rod.

where

ρ = fuel pellet density [kg m^{-3}]

c_p = specific heat [$\text{kJ kg}^{-1} \text{K}^{-1}$]

T = temperature [K]

t = time [s]

k = thermal conductivity [$\text{kW m}^{-1} \text{K}^{-1}$] and

q'' = volumetric heat generation rate within the fuel [kW m^{-3}].

The pellet thermal conductivity is a function of several variables including temperature, burnup, fuel porosity and composition. The thermal conductivity is highly dependent upon temperature (Fig. 3). This dependency must be considered in analysis, as the temperature across the radius of the fuel pellet varies by several hundred degrees (Fig. 2).

For a steady-state situation with circumferential symmetry, the heat conduction equation simplifies to:

$$\frac{1}{r} \frac{d}{dr} \left[k(T) r \frac{dT}{dr} \right] = -q''(r) [\text{kW m}^{-3}] \quad (2)$$

where r [m] is the radial location within a fuel pin.

For the special case of constant thermal conductivity and a uniform volumetric heat generation rate, the heat conduction equation for the radial temperature distribution in the fuel pellet further simplifies to:

$$\int_{T(r)}^{T_{\max}} k dT(r) = q'' \frac{R_{\text{fuel}}^2}{4} [\text{kW m}^{-1}] \quad (3)$$

The outer surface temperature of the fuel pellet serves as a boundary condition for analysis of heat transfer through the gas gap. The gap is very thin, such that heat transfer by convection of the gas molecules within the gap is negligible. Thermal conduction and radiative heat transfer are the primary heat transport mechanisms. The thermal resistance at the fuel-gap interface is largely a function of fuel surface and clad surface protrusions, which determine the amount of fuel-clad contact (Fig. 4), and also a function of contact pressure.

The heat transfer rate between the fuel and clad can be expressed as a function of the gap conductance, h_g .

$$q_g'' = h_g (T_{\text{fuel, outer}} - T_{\text{clad, inner}}) [\text{kW m}^{-2}] \quad (4)$$

$$h_g = \frac{k_{\text{gas}}}{\delta_{\text{eff}}} + \frac{\sigma}{\frac{1}{\epsilon_{\text{fuel}}} + \frac{1}{\epsilon_{\text{clad}}} - 1} \frac{T_{\text{fuel, outer}}^4 - T_{\text{clad, inner}}^4}{T_{\text{fuel, outer}} - T_{\text{clad, inner}}} [\text{kW m}^{-2} \text{K}^{-1}] \quad (5)$$

where

k_{gas} = thermal conductivity of the gas in the gap [$\text{kW m}^{-1} \text{K}^{-1}$].

δ_{eff} = effective gap width [m].

σ = Stefan-Boltzmann constant for radiative heat transfer [$\text{kW m}^{-2} \text{K}^{-4}$].

$\epsilon_{\text{fuel}}, \epsilon_{\text{clad}}$ = fuel pellet and clad emissivities [–].

$T_{\text{fuel, outer}}, T_{\text{clad, inner}}$ = fuel pellet outer and clad inner surface temperatures [K].

Fig. 3 Thermal conductivity of UO_2 (calculated with AREVA model in Todreas and Kazimi (2012), p. 370).

Fig. 4 Physical contact between fuel pellet and clad inner surface.

The first term on the right-hand side of the equation accounts for conduction while the second term represents the radiative heat transfer.

The conduction heat transfer rate from the clad inner surface to the clad outer surface is solved similarly as for the fuel. The volumetric heat generation rate, q''' [kW m^{-3}], within the clad is much smaller than that due to fission in the fuel, however it is often accounted for in fuel vendor calculations. Heat generation within the clad is mainly due to gamma-ray absorption and elastic and inelastic scattering of neutrons.

Convective heat transfer from the clad outer surface to the coolant occurs under turbulent flow conditions. The heat flux, q'' [kW m^{-2}], is expressed as the product of the heat transfer coefficient, h [$\text{kW m}^{-2} \text{K}^{-1}$], and the coolant temperature change from the heated surface to the bulk coolant temperature at the given elevation, z [m].

$$q''(z) = h(z) \Delta T(z) [\text{kW m}^{-2}] \quad (6)$$

For single-phase heat transfer, the forced convection heat transfer coefficient is appropriately selected to predict the change in sensible heat. Heat transfer by convection dominates over heat transfer by conduction for many coolants. For these coolants, the Dittus-Boelter correlation with a viscosity correction [Todreas and Kazimi \(2012\)](#) can be applied. Liquid metal coolants are a notable class of coolants for which a heat transfer coefficient must be chosen that accounts for both conduction and convective heat transfer, because conduction heat transfer is important even with significant convective heat transfer due to bulk motion of the coolant.

For two-phase heat transfer, a heat transfer formulation is applied that accounts for heat transfer both by bulk motion of the coolant (sensible heat) and by convective boiling (latent heat).

Reactors cooled by fluids other than water may have other steps in the energy conversion process, and additional components in their heat transfer systems, to transfer energy from the primary coolant to the coolant which delivers energy to power a turbine. In the energy flow of a gas-cooled power reactor, the steam generator is not needed if it is operating on the Brayton (gas) cycle.

Additional energy conversion processes take place in the vapor generation equipment and turbomachinery (turbines and pumps) within the heat transport systems. Power reactors operating on the Rankine (vapor) cycle have vaporization of liquid and condensation of the vapor. Most Rankine cycles use water as the working fluid. The steam generator vaporizes water into steam. Liquid metals including sodium or lead, or another fluid that does not moderate neutrons well, may be used in fast reactors. More exotic fluids such as mercury and potassium are used as the working fluid in compact space reactors.

Heat transfer system components in the basic electric power cycle

The basic electric power cycle is shown in [Fig. 5](#). The steam source for a power reactor is the Reactor Pressure Vessel (RPV) for a direct cycle reactor and the steam generator for an indirect cycle reactor. Direct cycle reactors include the BWR and the gas-cooled reactor,

Fig. 5 The basic electric power cycle for the rankine cycle.

which operates on the Brayton cycle. For the latter, hot gas from the core region flows directly to a gas turbine and the condenser and pump in **Fig. 5** are replaced by a compressor. Indirect cycle reactors include the PWR and a gas-cooled reactor operating on the Rankine cycle. For the latter, hot gas from the core region flows through a steam generator which boils water on the secondary side. The steam from this steam source then travels to a steam turbine. [Todreas and Kazimi \(2012\)](#) provide a convenient thermodynamic overview of the power cycles for various reactor types.

Heat transfer systems relevant to nuclear power generation

The systems discussed in this article are the Nuclear Steam Supply System (NSSS), the Reactor Coolant System (RCS) and the Emergency Core Cooling System (ECCS), with a focus on Light Water Reactor systems.

The NSSS is defined by the US NRC as “The reactor and the reactor coolant pumps (and steam generators for a pressurized water reactor) and associated piping in a nuclear power plant used to generate the steam needed to drive the turbine generator unit” ([US NRC, 2020a](#)). The RCS is defined as “The system used to remove energy from the reactor core and transfer that energy either directly or indirectly to the steam turbine” ([US NRC, 2019a](#)). Thirdly, the ECCS is stated to be “Reactor system components (pumps, valves, heat exchangers, tanks, and piping) that are specifically designed to remove residual heat from the reactor fuel rods in the event of a failure of the normal core cooling system (reactor coolant system)” ([US NRC, 2020b](#)).

The NSSS and the RCS share many of their major components. “RCS” appears far more often than “NSSS” in formal technical documents. In particular, NUREG-0800 ([US NRC, 2007](#)), which dictates the Standard Review Plan for US BWRs and PWRs and therefore provides guidance for the contents of Safety Analysis Reports and other documents submitted to the US NRC, refers exclusively to the RCS. For consistency, this article will describe the RCS and the ECCS and mention separately any significant aspects of the NSSS for heat transfer systems that are not discussed within the context of the RCS.

Reactor coolant system (RCS)

Description and functions

As described in the Introduction, the heat transfer systems have the functions of producing power and ensuring nuclear safety. With respect to the safety functions, the core and RCS are designed to enable operation such that no fuel damage occurs as a result of normal operation or a moderate frequency transient. By designing against fuel damage, the release of radioactivity is minimized and the nuclear safety goal of protecting the public’s health and safety is achieved. With respect to the power production, the core and RCS are designed to enable operation at rated core power and possibly load following or load maneuvering without core damage.

In a PWR, the RCS provides steam heat from the nuclear fuel to the steam generators. The RCS consists of the RPV, the steam generators, the reactor coolant pumps, the pressurizer and the connecting piping. Also termed the “primary loop” or the “primary system”, the RCS is illustrated in **Fig. 6**.

Depending on the particular plant, the RCS may have two or three or four primary loops. The most common configuration in the US is a Westinghouse four-loop plant. Each loop includes one steam generator and one reactor coolant pump. One loop is equipped with a pressurizer, which regulates the primary system pressure. Three-loop Westinghouse plants consist of three steam generators, three reactor coolant pumps and one pressurizer. Two-loop Westinghouse plants have two steam generators, two reactor coolant pumps and one pressurizer. Reactors designed by Combustion Engineering or Babcock and Wilcox have the one pressurizer and two steam generators. Different from the Westinghouse designs, two cold legs return from each steam generator to the RPV, for a total of four reactor coolant pumps in the primary system. See also [Brown \(2021\)](#).

In current BWRs, the steam is generated within the RPV. Termed “direct cycle”, the BWR does not need an external steam generator as the PWR does. The NSSS consists of the RPV, the nuclear core, the turbines and associated piping. The RCS consists of the

Fig. 6 Simplified schematic of a PWR RCS.

NSSS plus the condenser downstream of the turbines, the return feedwater pumps and associated piping. A wet steam mixture exits the top of the core and is directed into moisture separators and dryers. The dry steam has a quality of greater than 99.5%, suitable for entering the steam turbines, which power the generators to produce electricity. The expanded steam leaving the turbine is condensed and then returned to the RPV through feedwater pumps. [Fig. 7](#) shows the NSSS and the RCS for a BWR.

Water droplets in the wet steam leaving the top of the core are separated from the steam by the steam separators and dryer, located above the core and within the RPV. This water represents a significant fraction of the coolant within the RPV. A recirculation flow path internal to the RPV is established such that this water mixes with incoming feedwater flow and is returned to the core inlet. The separated water droplets do not have enough momentum to overcome pressure losses and recirculate. Therefore, upon separation from the steam flow, the water travels through the downcomer and into jet pumps, which add momentum. The returning water is the lower pressure “suction flow” in [Fig. 8](#).

Recirculation pumps take water from the downcomer, the annular region between the core shroud and the inner surface of the RPV wall, and direct this flow to the inlet of the jet pumps as the driving flow for coolant recirculation. [Figs. 8 and 9](#) show the components that enable internal recirculation. See also [Hamon \(2021\)](#).

The jet pump principle and the concept of recirculation within the RPV are unique to the BWR designs. Key features are that the jet pump contains no moving parts and can provide flow at the full range of flow rates to enable load following. The jet pumps provide enough momentum to supply about two-thirds of the recirculation flow within RPV ([General Electric, 1980](#), pp. 1–4). The principle is momentum exchange between water flows. The recirculation pumps provide the higher pressure “driving” flow into the jet pump driving nozzle ([Fig. 8](#)). The driving flow is accelerated by the area reduction at the nozzle outlet. The “suction” flow is the water returning from the separators and dryers. The suction flow enters at a lower pressure, which is further lowered as it is accelerated in the converging section outside of the driving fluid nozzle. The suction flow and the driving flow mix in the “mixing section”. Momentum transfer due to fluid mixing, along with development of a new velocity profile, cause a pressure recovery. The diffuser downstream of the mixing section slows the relatively high-velocity flow stream, converting part of the dynamic component of total pressure to static head, and thereby providing the flow mixture with appropriate velocity and head to flow into the lower head and return to the reactor core.

A key advantage of the recirculation concept is that regulation of the core power can be achieved by changing the speed of the recirculation pumps. A change in pump speed causes a change in the coolant flow rate through the core. With a higher or lower flow

Fig. 7 Simplified schematic of a BWR reactor coolant system.

rate into the core, the amount of liquid coolant in the core region is changed. This, in turn, affects the amount of neutron moderation, thereby changing the core's reactivity and the core power level. This ability to change the core power without moving control rods or adding/deleting chemical shim as in PWRs (Brown, 2021) allows for more efficient usage of the nuclear fuel.

As described by Lahey and Moody (1993), the turbine is "slaved" to the reactor, meaning that the turbine demand follows the reactor steam output. This allows for the RPV pressure to remain approximately constant. To accommodate load changes (changes in steam demand by the turbine), the BWR can vary the reactor power level by flow control of the reactor coolant through the core, as described in the previous paragraph. This flow control concept is illustrated in Fig. 10.

The above discussions have been for active plants that require powered pumps for forced circulation of the coolant and heat removal by forced convection heat transfer. Reactor design techniques to promote natural circulation flow and natural convection heat transfer has matured to the extent that a reactor cooled by natural circulation of the coolant (no pumps!) has been Design Certified by the US NRC. This design is discussed further in the section on passive reactors.

Design requirements

The main objective of the thermal and hydraulic design of the core is to provide sufficient heat removal for the core power distribution such that fuel integrity is not sacrificed. As described in the Introduction, the heat transfer systems have functions to both promote power production and maintain nuclear safety. The design requirements for the RCS, therefore, have both safety design bases and power generation design bases. The following are typical safety and power generation criteria that must be met:

- Fuel integrity can be maintained for normal operation, Anticipated Operational Occurrences (AOOs) and transients considered within the NUREG-0800 Chapter 15 basis (US NRC, 2019b).
- The reactor can be maintained in a safe state for events within the Design Basis Event range.
- For BWRs: The reactor shows no signs of oscillations that could threaten the integrity of the fuel or the primary pressure boundary.

The fuel integrity can be maintained as long as the heat rate from a fuel rod does not exceed some limit. Tong and Weisman (1996) describe the major factors in maintaining fuel integrity:

Fig. 8 Jet pump principle (General Electric Company, 1980). Courtesy of GE Hitachi Nuclear Energy Americas LLC.

Fig. 9 BWR recirculation system with jet pumps (General Electric, 1980). Courtesy of GE Hitachi Nuclear Energy Americas LLC.

Fig. 10 Flow control concept of a direct-cycle BWR.

- Fuel centerline temperature well below the fuel melting temperature;
- Heat flux on the clad outer surface below a limiting value determined by the coolant conditions;
- Fuel burnup and fission gas release limited to avoid excessive internal pressure in the clad and clad creep or embrittlement;
- Heat flux low enough to avoid unacceptable behavior of the clad during postulated accident conditions;
- Appropriate power density; and
- Limitation on the rate of power change to avoid development of local stresses that are too large to be accommodated.

The limiting core power level can be determined by knowing where the “hot spot” is in the core, that is the location of highest temperature, and evaluating the heat removal rate needed to adequately cool this hot spot. Thus, knowledge of the radial and axial temperature distributions of the core are required. It should be noted that a reactor core typically experiences a very small fraction of fuel rods that “fail” during operation, or release radioactivity to the RCS. The US nuclear industry has led a successful campaign to reduce the fraction of “leakers” to on the order of less than 10 in 50,000 or 60,000 rods in the core.

Major heat transfer components of the RCS

The heat transfer phenomena and operation of the major RCS components in PWRs and BWRS are described below.

PWR heat transfer components of the RCS

PWR steam generator

The high-temperature coolant leaving the RPV passes through the PWR steam generator depositing the heat used to create steam for the main turbines. The steam generator, therefore, is a tube-and-shell heat exchanger designed to use heat from the higher temperature primary fluid on the tube-side to vaporize liquid on the secondary side into steam. The steam generator is a vertically-mounted pressure vessel with a tube bundle, through which the primary coolant travels, and steam separators and dryers for some designs. To be noted, some Russian-designed PWRs (VVERs) employ horizontal tube-and-shell heat exchangers as their steam generators. In a closed-loop design, the primary coolant makes two passes through the Westinghouse-type inverted U-tube steam generator and a single pass through the Once-Through Steam Generator design before being pumped back to the RPV. **Fig. 11** shows the evaporator section, housing the tube bundle, and the steam drum section, housing the moisture separation equipment for

Fig. 11 Westinghouse steam generator (Cummins and Matzie, 2018).

a Westinghouse design. Fig. 12 illustrates the Babcock and Wilcock Once-Through Steam Generator design. Combustion Engineering employs a third design for its CE System 80 steam generator, with unique features being an axial flow feedwater economizer and steam outlet nozzles with venturi flow restrictors (Cummins and Matzie, 2018).

The higher-temperature primary coolant travels through a bundle of several thousand tubes. Heat is transferred from the primary coolant by thermal conduction through the tube walls to the secondary coolant. To minimize thermal resistance, the tubes are thin-walled and made of a high thermal conductivity material such as Inconel, a nickel alloy.

Most steam generators are natural circulation units on the secondary side. The secondary-side feedwater enters the steam generator subcooled. Heat from the primary side goes toward heating the secondary side coolant to the saturation temperature. As the secondary side water travels further along the tube bundle, the water vaporizes. The decrease of coolant density along the flow path promotes the natural circulation flow. In the inverted U-tube design, the water passes through steam separators and dryers before exiting to the main turbines. In the B&W design, the steam is superheated near the top of the tube bundle and exits with as much as 33°C (60°F) superheat. The thermal efficiency of the B&W design is comparable to that of other LWRs.

The primary and secondary flows are in countercurrent flow in both steam generator designs. Care must be taken in the design stage to have a primary-to-secondary side temperature difference for efficient heat transfer along the entire tube length. Fig. 13 illustrates the temperature difference in a once-through steam generator. The secondary-side water enters subcooled but holds at saturation temperature at the secondary-side pressure for most of the tube bundle length. (This figure does not include the superheater at the top of the tube bundle.) The primary-side water is subcooled for the entire tube length because of the higher primary-side pressure. The pinch point, where the two temperatures are closest, is a key factor in determining an appropriate tube length and heat transfer area.

For an inverted U-tube, the same type of diagram reveals that the flow is co-current along the riser side of the steam generator tubes and counter current along the second half of the tubes (Fig. 14). The x-axis is shown as tube axial location instead of enthalpy. The primary-side coolant is once again subcooled for the entire length. The pinch point is at P1 for the original design. If a preheater is added, the secondary fluid in the preheater section follows line B.

Fig. 12 B&W once-through steam generator (Cummins and Matzie, 2018).

Fig. 13 Temperature variation in a once-through steam generator.

Fig. 14 Temperature variation in a U-tube steam generator.

The heat transfer resistance from primary to secondary side is the sum of the thermal resistances of the primary-side forced convection heat transfer, the tube wall conduction, fouling on the tube outer surface, and the secondary-side heat transfer.

$$\frac{1}{U} = \frac{A_{SGtube,outer}}{h_{inner}A_{SGtube,inner}} + \frac{r_{SGtube,outer} - r_{SGtube,inner}}{k_{SGtube}} \frac{A_{SGtube,outer}}{A_{SGtube,mean}} + f + \frac{1}{h_{outer}} \quad (7)$$

where

A = heat transfer area

h_{inner} = the primary-side forced convection heat transfer coefficient

r = tube radius

f = fouling factor

h_{outer} = the secondary-side heat transfer coefficient

The length on the secondary side which is not in boiling must be known. For this section, a forced convection heat transfer coefficient is used. Along the boiling length of the secondary side, boiling coefficients are appropriate.

Fouling on the outer side of the tubes must be considered. Primary-side fouling is generally considered negligible because of the extremely high level of water chemistry control. However, purity on the secondary side is not as high and some fouling can be present. To more accurately assess heat transfer rates, a thermal resistance term for fouling must be included, as shown above.

Operational issues for the U-tube steam generators include localized corrosion in low velocity zones on the secondary side where sludge can deposit. Improvements to the secondary-side water treatment have largely eliminated this problem. The addition of baffles to increase the velocity in these areas have also reduced the problem. In the 1970s, Primary Water Stress Corrosion Cracking (PWSCC) of Inconel 600 tubes was observed. Tube cracking was found in areas of high stress, such as in the 180° bend of the first row, the tightest row, of tubes and where tubes transition in size at the tube sheet entrance. Changes in the manufacturing processes and the use of Inconel 690, which is more resistance to PWSCC, have reduced this problem.

The once-through steam generators have shown problems with thermal stresses, since the straight tubes have less freedom to expand axially than the U-tube bundles. These long tubes may expand several inches when heated. The higher section of the tubes is at about the primary temperature while the lower portion is at the saturation temperature. Greater care is now given to minimize the difference in amount of thermal expansion of the tube bundle and the shell, especially during full-load operation (Tong and Weisman, 1996).

PWR pressurizer

The pressurizer has the function of regulating the primary-side pressure. The pressure is maintained at a set value during steady-state operation and pressure transients are mitigated during transients and some accidents. Only one pressurizer is needed in the primary side since the RCS should be full of water everywhere except in the vapor space of the pressurizer. Therefore, a change in pressure in the pressurizer will propagate throughout the entire RCS (nearly) immediately because water is essentially incompressible.

Fig. 15 shows a schematic of a Westinghouse-design pressurizer. The vessel is a tall, narrow vessel to enable water level change, and thereby, a change in elevation head (ρgh). Designs by other vendors are very similar. To maintain a constant operating pressure, the pressurizer water is to be kept at saturation temperature by electric heaters installed in the bottom of the pressurizer. To mitigate a pressure decrease, the heaters can heat the water and increase vapor pressure.

The pressurizer water level can increase or decrease in response to a change in primary water temperature change. This water level change affects the vapor space pressure. To mitigate a pressure rise, sprays at the vessel top release water droplets to condense steam and decrease the vapor pressure. The spray water source is one of the cold legs, which supplies water at less than saturation temperature. As a last resort, if the sprays are unable to keep the pressure below a setpoint value, then relief valves can be opened at the top of the pressurizer to vent steam into the containment.

The relevant heat transfer processes in the pressurizer are:

- vaporization from the water surface due to depressurization (and water level decrease)
- condensation in the vapor space due to pressurization (and water level rise)
- steam condensation onto water droplets due to operation of the sprays
- condensation on the pressurizer vessel wall inner surface.

Fig. 15 Westinghouse pressurizer (Cummins and Matzie, 2018).

The control volume approach with the assumption of thermodynamic equilibrium between the vapor and liquid can be assumed for mild transients (Todreas and Kazimi, 2012, p. 340). For more rapid transients, the two phases cannot be assumed to be in equilibrium and an analysis by a method such as the two-fluid model gives more accurate results.

Condenser

The description of the condenser herein is common to PWR and BWR cycles.

The condenser is a device that transfers heat from the steam exhausted from the main turbines to a secondary-side fluid within the condenser. The steam expands in the turbine from a very dry state to a wet steam mixture. This wet steam mixture no longer carries enough energy to efficiently transfer further thermal energy to the turbine. Rather, the wet steam is condensed in the condenser to single-phase liquid water, pumped back to the secondary-side pressure, and returned to the steam generator.

The condenser is an essential heat transfer system because it brings the wet steam to a state that it can be pumped up to the secondary-side pressure and returned to the steam generator as slightly subcooled feedwater. The relevant heat transfer mode is phase change (wet steam to single-phase liquid water). To maximize the amount of work done by the turbine and increase the thermal efficiency of the Rankine cycle, the condenser operates at a partial vacuum (0.067 MPa, or 20 in. of mercury, or less). For a condenser operating at 0.02 MPa (5.9 in. of mercury), the corresponding saturation temperature is about 60 °C. The condenser is usually a single-pass heat exchanger with thousands of straight-through tubes.

Cooling towers and ultimate heat sinks

An Ultimate Heat Sink is the destination for rejection of unused thermal heat from the power plant. A cooling tower is a heat exchanger that transfers the condenser rejection heat into the air instead of into a body of water. The description herein of these components is common to both PWRs and BWRs.

The heat removed from the steam by the condenser is no longer used in the Rankine cycle and is exhausted to the environment. The Ultimate Heat Sink is either a cooling tower or a large body of water such as a lake, river or ocean. Rejection of the heat from steam condensation may be done in one of three ways (World Nuclear Association, 2020):

- The simplest method is “direct” or “once-through” cooling. If the power plant is near a large body of water, the heat may be removed by running water through the condensers and discharging the heated water back to the body of water.
- Another method is by dry cooling. This method, by which air removes the heat by forced convection, is less commonly employed. The air flow may be in a closed loop. This method would be used only by plants not located near a large body of water.
- The third method is “wet recirculating” or “indirect cooling” (US Department of Energy, 2011). In wet recirculating systems, the water in the condenser which removes heat from the steam is pumped to a cooling tower. The heat from the warm water is removed by air flowing upward through the cooling tower. Evaporation is the main heat transfer mode, with a smaller rate of heat removal by forced convection to the air flow. A small fraction of the warm water, 3–5% per the World Nuclear Association (2020), evaporates from the cooling tower and appears above the cooling tower as the white vapor plume which characterizes the cooling tower appearance. The draft induced by reduced air density and buoyancy of the lighter air provides natural pumping action for these flows. Completing the cycle, the cooled water is returned back to the condenser. Due to the evaporation of some of the cooling water, buildup can occur of minerals and sediment in the water that could degrade performance. A fraction of the cooling water is continuously removed and replaced to prevent buildup and performance degradation.

To be noted, this natural draft reduces the amount of pumping power required and involves only nonradioactive water/steam. This attribute of energy conservation may seem ironic because of the “negative” image of nuclear power that the hyperbolic cooling towers can symbolize.

- The US Department of Energy (2011) also lists a fourth method, referred to as a “cooling pond”. A cooling pond is essentially the same as a wet recirculating system, however, natural conduction and natural convection heat transfer from the water to the atmosphere is used together with evaporation to cool the recirculating water.

According to the US Department of Energy (2011), as of 2011, 38.1% of US nuclear power plants used once-through systems, 0% used dry cooling systems, 43.6% of US nuclear power plants used wet recirculating systems and 18.3% used cooling ponds.

It should be noted that all of these systems are designed such that the heat rejected to the environment, be it a body of water or the air, is not harmful to the surroundings.

PWR main coolant pumps

The PWR main coolant pumps are all centrifugal pumps that operate according to a pump curve as that shown in Fig. 16. They are single-stage, vertically mounted pumps designed to move large flow rates of primary cooling water (as much as 6.2 m³/s, or 100,000 gpm!) through the primary loop under high pressure and temperature conditions. The optimal operating point for the pump is at the intersection of the pump curve and the system characteristic curve.

The pumps must have sufficient Net Positive Suction Head (NPSH) at the pump suction (pump inlet). The pressure at the entrance to the impeller of a centrifugal pump is lower than that at the pump suction. Cavitation, or bubble formation, at the impeller is possible if the local pressure falls below the vapor pressure of the fluid corresponding to its local temperature. Cavitation is detrimental to the performance and integrity of the pump and therefore the pumps must be operated with sufficient NPSH to avoid this situation. Locating the pumps on the cold legs is one means to increase the NPSH on the pumps and avoid cavitation.

Fig. 16 Pump curve for PWR main coolant pumps.

PWR piping and valves

The piping and valves on the primary loop must withstand the high temperature and pressure environment for the life of the reactor. To meet this requirement, they are made of carbon steel with a stainless steel clad or are made of stainless steel. The pressurizer surge line from the main steam line and other pressurizer connections and lines are of austenitic stainless steel. Most joints and connections are welded as permanent connections instead of flanged.

Being made of metal, all of these components and the RPV are good thermal conductors. As such, their outer surfaces will be within a few degrees of the temperature of the primary flow. Heat loss to the surrounding containment gas space would be by thermal radiation and natural convection and would be significant. These heat losses must be reduced to enable more efficient use of fission heat and to maintain the containment conditions within acceptable ranges.

Piping and valves that operate at high temperature are insulated to reduce heat losses. To prevent the development of high thermal stress spots due to rapid changes in fluid temperature during a transient, thermal sleeves are installed. The RPV is often insulated with a reflective metal insulation system (US NRC, n.d.).

BWR heat transfer components of the RCS

BWR steam separators and dryers

In contrast to the indirect cycle of the PWR, the coolant in a direct-cycle BWR is vaporized within the active core region by heat transfer from the clad outer surface. The BWR does not employ steam generators external to the RPV.

To ensure adequate cooling of the fuel, the core and RCS are designed such that the fuel rods are always covered with water. The upper portion of the active core is within a two-phase steam-water mixture: the fuel rods are “wetted”, or covered by a liquid film, while the bulk of the fluid is a two-phase steam-water mixture. Fig. 17 (Young, 2021) illustrates the two-phase configuration in a BWR core region. Because the heat transfer coefficient associated with water vaporization is very high, the fuel rods are sufficiently cooled when they are wetted.

The basic physics promotes this favorable distribution of steam and water within the two-phase region. Following the path of least flow resistance, the higher velocity steam flows through the center of the flow channels and away from the fuel rods which impose a frictional wall resistance. The lower velocity liquid is pushed away from the flow channel center and toward the fuel rod outer surfaces. Some water is also entrained as droplets by the steam to form a two-phase wet steam mixture. The requirement that the fuel be wetted places a limitation on the core height. The core height is specified such that the water inventory does not boil off and result in dryout of the clad outer surface. With this two-phase distribution, the two-phase portion of the active fuel region is efficiently cooled by forced convection boiling even at the core exit elevation.

Fig. 17 Two-phase configuration in the BWR core region (Young, 2021).

Wet steam should not be ingested by the turbines due to the high potential for turbine blade damage by water droplets. The quality of the steam at the core exit is low, ranging between about 10–15% depending on the reactor. To dry the steam, separators and dryers are installed in the BWR RPV above the core.

BWR condenser

The description of the condenser is common to PWR and BWR cycles. The reader is referred to the earlier discussion of the condenser for the PWR RCS components.

Cooling towers and ultimate heat sink

The description of the cooling towers and Ultimate Heat Sink is common to PWR and BWR cycles. The reader is referred to the earlier discussion of these components for the PWR.

BWR pumps

The BWR uses Feedwater Pumps to return primary coolant (“feedwater”) from the condenser back to the RPV, Recirculation Pumps to provide driving flow to the recirculating coolant within the RPV downcomer, and jet pumps to provide most of the motive force for recirculating flow. The Feedwater Pumps are steam-driven pumps with a capacity less than that of the pumps for a comparable PWR due to the recirculating flow within the RPV. They operate at about half the pressure of the PWR Main Coolant Pumps. The Recirculation Pumps and jet pumps have been described in detail earlier.

BWR piping and valves

The piping and valves on the primary loop must withstand the high temperature and pressure environment for the life of the reactor. To meet this requirement, they are made of carbon steel with a stainless steel clad or are made of stainless steel. Most joints and connections are welded as permanent connections instead of flanged.

Being made of metal, all of these components and the RPV are good thermal conductors. As such, their outer surfaces will be within a few degrees of the temperature of the primary flow. Heat loss to the surrounding containment gas space would be by thermal radiation and natural convection and would be significant. These heat losses must be reduced to enable more efficient use of fission heat and to maintain the containment conditions within acceptable ranges. Piping and valves that operate at high temperature are insulated to reduce heat losses to the containment.

Heat removal systems during normal shutdown and following primary system breach

As mentioned earlier, the goal of nuclear safety is to protect the public’s health in the unlikely event of a release of radioactivity. Radioactive fission products will not be released if the fuel integrity is maintained. To prevent fuel failure and maintain a safe state in a nuclear system, system components must be kept within acceptable temperature limits. Adequate heat removal from the nuclear fuel by heat transfer systems prevents fuel failure and subsequent release of radioactivity, and thereby, promotes fulfillment of the nuclear safety goal.

Adequate heat removal is achieved by maintaining the RPV water level above the top of the active fuel at all times, including after termination of the nuclear fission reaction by control mechanisms. The heat removal mechanisms during normal operation have been described earlier. Additional heat removal systems are in place for normal shutdown cooling at high and low pressure and the ECCA. Each of these systems is described below.

From a heat transfer perspective, these systems are reconfigurations of a Rankine system components (piping, heat exchangers, turbines, pumps) in order to transport the core heat under a variety of thermodynamic conditions (ranging from high pressure to low pressure) and flow conditions (ranging from steam flow rate at full core power to steam flow rate corresponding to decay heat rate). Some configurations involve only single-phase heat transport (forced convection or natural convection heat transfer) while others involve two-phase heat transport (forced convection with boiling and/or condensation). The PWR steam generators were noted earlier to involve natural circulation. The technology to enable natural circulation flow and natural convection heat transfer in reactors has matured to the extent that a fully passive reactor has been Design Certified by the US NRC. These so-called “passive” systems belong in a class of their own and are described in a later section.

Normal shutdown cooling at high pressure for PWRs

Under normal shutdown cooling, the nuclear fission reaction has been essentially terminated and the steam generation rate in the steam generators is greatly reduced. The secondary coolant heat removal system is rerouted such that the turbine is bypassed and steam is directed from the steam generators to the main condenser. The condensate and feedwater systems return coolant to the steam generator secondary side as in normal operation. All systems are operating at much lower flow rates than for operation at reactor power because the largest contributor to heat generation is now heat released from decay of radioactive fission products.

Normal shutdown cooling at low pressure for PWRs

After an initial cooldown to 177 °C (350 °F) and depressurization to about 2.8 MPa (400 psig) (US NRC, n.d.), the Residual Heat Removal (RHR) system takes over to provide shutdown cooling. The steam generators and secondary loop used in power operation are no longer employed. Instead, primary reactor coolant from a hot leg is directed to RHR heat exchangers and returned through cold legs to the RPV. The secondary-side heat removal is provided by a closed-loop, single-phase system, named the Component Cooling Water System (CCWS), which rejects heat to a tertiary loop, and finally to the Ultimate Heat Sink. All heat transfer is single-phase, forced convection heat transfer except as dictated by the equipment for heat transfer to the Ultimate Heat Sink.

Normal shutdown cooling at high pressure for BWRs

For normal shutdown cooling at high pressure, earlier vintage BWRs and some newer passive BWR designs are equipped with Isolation Condensers, while later non-passive BWRs use the Reactor Core Isolation Cooling (RCIC) System.

In the Isolation Condenser system, an elevated, vertical tube bundle takes steam from the RPV into the top of the tube bundle and returns condensate from the bottom of the tube bundle back to the RPV. For this natural circulation loop, a small pressure difference drives flow to the condenser and gravity returns condensate to the vessel. As its name implies, the system was designed for use when the RPV is “isolated” from the main steam turbines. The tube bundle sits in one of several water compartments outside of containment. Heat from the condensed steam boils water on the secondary side and the nonradioactive steam is vented to the Ultimate Heat Sink. A key feature of the Isolation Condenser System is that heat is that decay heat is transferred outside of containment while no coolant mass leaves the primary system.

The RCIC System takes decay heat steam from the RPV to provide motive energy to a Terry steam turbine. The turbine is on the same shaft as the RCIC pump and therefore powers the pump to provide cooling water to the RPV. The RCIC pump takes suction from the Condensate Storage Tank. If the RCIC System runs long enough to deplete the Condensate Storage Tank, the pump suction is realigned to the bottom of the Suppression Pool water volume in containment. Steam flowing into the Terry turbine is exhausted as wet steam to the Suppression Pool. The RCIC System gained recent attention due to performance far in excess of its expected capabilities during the accidents at Fukushima Dai-ichi Units 2 and 3 (Solom and Vierow Kirkland, 2015). Since RCIC turbine steam is vented to the Suppression Pool and RCIC pump suction is from the Suppression Pool, a cooling system is in place to transfer heat from this pool to the Ultimate Heat Sink and maintain acceptable containment pressure.

Normal shutdown cooling at low pressure for BWRs

The RHR System provides cooling once the primary system has been depressurized to about 0.95 MPa (125 psig) and undergone an initial cooldown. Configured with the recirculation loops shown in Fig. 9, the RHR System removes decay heat by passing primary coolant water through RHR heat exchangers and returning the cooler water back to the RPV. The RHR shutdown cooling suction line is aligned with the suction side of one of the recirculation pumps to extract primary coolant. After passing through the RHR heat exchangers, the coolant is returned to the RPV either through the recirculation line on the discharge side of a recirculation pump or via a main feedwater line.

Emergency core cooling systems (ECCS)

Following a hypothetical failure of the primary pressure boundary, water is lost from the RCS and core cooling must be restored. After the Reactor Protection System has served to terminate the nuclear fission reaction, Engineered Safety Features (ESF) are called upon in LWRs to provide continued heat removal. The ESFs are safety systems that provide a safety function to mitigate consequences of accidents that may cause major fuel damage and cannot be accommodated by the Reactor Protection System alone.

Adequate heat removal is achieved by:

- Terminating the heat generation. Heat generation through the nuclear fission reaction can be stopped by control mechanisms. However, heat generation by radionuclide decay of fission products in the fuel cannot be stopped. Therefore, an additional function is needed:
- Providing heat removal

The ESF which provides this heat removal is the ECCS.

ECCS design bases

According to 10 CFR 50, Appendix K (US NRC, 2017a), the ECCS must be able to achieve its function with certain equipment damage. The single-failure criterion states that, “Single Failure Criterion. An analysis of possible failure modes of ECCS equipment and of their effects on ECCS performance must be made. In carrying out the accident evaluation the combination of ECCS subsystems assumed to be operative shall be those available after the most damaging single failure of ECCS equipment has taken place.”

The acceptance criteria for LWR ECCS as codified in 10 CFR 50.46 (US NRC, 2017b) as:

- Peak fuel clad temperature is not to exceed 1200 °C (2200 °F).
- Total cladding oxidation is not to exceed 0.17 times the total clad thickness.
- Total amount of hydrogen generation from cladding chemical reaction is not to exceed 0.01 times the total hydrogen generation if all of cladding were to react.
- Any core geometry changes must leave core in a coolable state.
- Appropriate long-term cooling must be provided to keep the core at acceptably low temperatures

The first two criteria assure that the cladding remains sufficiently intact to retain the fuel pellets and radioactive fission products. The third criterion assures that hydrogen gas will not be generated in amounts that could combust.

ECCS for PWRs

In a PWR, the ECCS both provides core cooling and supplies additional neutron poisons. The latter function ensures that the core is in a shutdown mode by adding large amounts of borated water to the solid water system. This second function is accomplished by the injection of large amounts of cool, borated water into the RCS to help ensure that the reactor remains shutdown. This borated water source is called the Refueling Water Storage Tank (RWST).

Multiple systems are available to provide core cooling water and ensure adequate cooling, as determined by heat and mass balances. All PWR ECCS include pressurized Safety Injection Tanks (SITs) and high-pressure and low-pressure safety injection (HPSI and LPSI) pumps. The cooling water is injected via a hot leg, a cold leg or directly into the RPV, depending on the reactor design and accident stage.

A Loss of Coolant Accident (LOCA) scenario can be divided into the ECCS injection phase and the ECCS recirculation phase. The ECCS injection phase involves ensuring adequate water supply and heat removal (heat and mass balance). During a large-break LOCA, the primary system rapidly depressurizes and water is supplied by the safety injection accumulators once the primary pressure falls below the accumulator pressure. Both HPSI and LPSI pumps are aligned to deliver water from the RWST to the primary side. During a small-break LOCA, because of the slower loss of coolant inventory from the primary side, an energy balance is achieved between the heat generation rate in the core and the total of heat loss rates through the break, steam generators and other systems. Makeup coolant can be provided in some PWR designs by the HPSI pumps.

After the RWST supply has been depleted, the recirculation mode of ECCS operation is commenced. The containment sump has collected a large volume of water discharged during the LOCA and from operation of containment sprays. The LPSI pumps are reconfigured to take suction from the containment sump instead of from the RWST. For a large LOCA, the recirculation will be in a low-pressure mode, while for a small LOCA, the system may be operating at either high pressure or low pressure. Heat exchangers, if available for operation, may be used in the low-pressure safety injection system to transfer heat to the Ultimate Heat Sink via intermediate heat transfer systems.

ECCS for BWRs

In a BWR, the ECCS includes a system that injects coolant via piping or spray nozzles into the RPV at high pressure; one or more systems which can inject or spray coolant into the RPV at low pressure; and an Automatic Depressurization System (ADS). The High-Pressure Coolant Injection (HPCI) system and the High-Pressure Core Spray (HPCS) system have pumps that can overcome the large pressure difference to provide coolant at up to the normal operating pressure of the RPV. The Low-Pressure Coolant Injection (LPCI) system and the Low-Pressure Core Spray (LPCS) are low pressure systems intended to respond to large LOCAs by supplying makeup coolant at larger flow rates than the high-pressure systems can. The ADS depressurizes the primary side, enabling the low-pressure ECCS systems to actuate and provide core makeup water when the high-pressure systems are unable to adequately maintain the cooling function.

Mass and energy balances dictate which ECCS systems are needed when. While the low-pressure systems can add coolant more rapidly to the primary system, the trade-off of rapidly releasing primary coolant to the containment that are associated with ADS operation must be considered when determining when to transition from high-pressure ECCS systems to low-pressure ECCS systems. Brief descriptions of the physics of each type of ECCS subsystem follow. Fig. 18 shows a schematic of the ECCS for a BWR/6, a more recent BWR design.

High-pressure ECCS cooling systems in BWRs

The HPCS is employed at high pressure in the more recent BWR/5 and BWR/6 designs. The intention of the HPCS is to provide makeup water and depressurize the primary system. The HPCS prevents fuel failure if the coolant level were to fall below the Top of Active Fuel by spraying water droplets down onto the core, thereby maintaining adequate cooling of the fuel clad. The spray is injected from a ring of nozzles above the reactor core. The water droplets that fall on the fuel assemblies remove heat by forced convection and vaporization. The HPCS reduces the primary pressure by steam condensation on the water droplets. Heat and mass are transferred from the primary system to the Suppression Pool in the containment by opening of the primary Safety/Relief Valves. While most of the normal shutdown systems discussed earlier were closed systems, the HPCS initially operates as an open loop, drawing water from the Condensate Storage Tank. If the Condensate Storage Tank water supply runs low, water is taken from the Suppression Pool and the system becomes closed. Suppression Pool cooling becomes necessary to transport heat to the Ultimate Heat Sink.

Fig. 18 BWR/6 ECCS (Lahey and Moody, 1993). Copyright 1993 by the American Nuclear Society, La Grange Park, Illinois.

The HPCI System is employed at high pressure in the earlier BWR/3 and BWR/4 designs. The HPCI System cools the core by forced convection heat transfer and does not have the same depressurization function at the HPCS. Similar to the HPCS, the HPCI System initially runs on an open cycle. The HPCI System takes water from the Condensate Storage Tank and injects into the RPV through one of the main feedwater lines. The HPCI System pump is powered by a steam turbine that ingests steam from one of the main steam lines and exhausts to the Suppression Pool. Heat and mass are transferred from the primary system to the Suppression Pool in the containment by opening of the primary Safety/Relief Valves. If the Condensate Storage Tank water supply runs low, water is taken from the Suppression Pool and the system becomes closed. Suppression Pool cooling becomes necessary to transport heat to the Ultimate Heat Sink.

Low-pressure ECCS cooling systems in BWRs

All BWRs have low-pressure systems to provide coolant makeup in response to a large LOCA. Except for Dresden I, all plants can depressurize via Safety/Relief Valve discharge to the Suppression Pool.

All BWRs have a LPCS system that delivers water from the Suppression Pool to one or more spray spargers located above the reactor core. Similar to the HPCS, the function of the LPCS System is to prevent fuel failure if the coolant level were to fall below the Top of Active Fuel by directing jets of water into the fuel assemblies, thereby maintaining adequate cooling of the fuel clad.

The LPCI System in BWR/3 and later designs provides the ability to "flood" the core, that is, supply water to raise the coolant level above the top of the core. The probability of fuel failure is much lower when the core is flooded because fuel is in contact with coolant at all locations and should be adequately cooled by forced convection heat transfer or subcooled boiling. Water is supplied by the Suppression Pool to the RPV. In some BWR/3 designs, the LPCI System is a dedicated system that injects water via one of the recirculation loops. In later BWR/3 designs and all BWR/4 to BWR/6 plants, the LPCI function is one of the functions of the "multi-mode" RHR System. That is, the RHR System equipment is used for LPCI operation. Coolant is injected via one of the recirculation loops or directly into the RPV, as shown in Fig. 18.

Heat removal systems for passive light water reactors

Passive systems are those that rely on natural forces such as gravity and small pressure differences to drive natural circulation flow and heat transfer and do not depend on operator actions. The use of natural forces promotes increased system reliability. Passive

systems are usually simpler in design, have fewer parts for easier/lower cost maintenance and do not depend on active power sources for heat removal. Differing from active systems which often have forced convection as the dominant heat transfer mode, the heat transfer modes in many passive systems are natural convection heat transfer or condensation of steam on cool containment surfaces or in submerged tube bundles.

A key feature of reactor designs with passive safety systems is large elevated pools of water that can drain into the RPV to supply core coolant. They may also have large heat transfer surfaces, such as the inner surfaces of containment structures or tube bundles, on which steam released from the primary or secondary loop can condense and transfer heat outside of containment.

Passive safety features of heat transfer systems in leading PWR and BWR designs are summarized below.

AP1000 passive heat transfer systems

The AP1000 was designed by Westinghouse Electric Company and has had four units operational in China since 2018, with two more units nearing completion in the US (Vogtle site). It is a Gen III+ reactor with a rated power output of 1100 MWe (Cummins and Matzie, 2018). Figs. 19 and 20 illustrate the AP1000 passive safety systems for core cooling and containment cooling respectively.

The AP1000 achieves long-term passive heat removal with a Passive Residual Heat Exchanger (PRHR). The PRHR employs a large heat exchanger in an elevated water pool in containment, the In-Containment Refueling Water Storage Tank (IRWST). The PRHR heat exchanger is a large C-shaped tube bundle that is connected at the top to a primary system hot leg by an inlet line that is always open during operation and to cold legs from the bottom. The PRHR operates at primary-side operating pressure to remove decay heat. At least one valve on the return line opens to enable natural circulation flow of single-phase water. Denser water cooled in the PRHR heat exchanger drains to the cold legs, promoting flow of hotter, less dense water from the reactor core to the PRHR inlet. The heat is transferred to the IRWST. Secondary-side heat transfer is initially natural convection until the IRWST water reaches saturation temperature. Steam produced by secondary-side boiling is vented to the containment gas space.

The Passive Containment Cooling System (PCS) removes heat from containment to avoid exceeding containment design pressure and temperature limits. Steam from the IRWST and/or from a LOCA condenses on the cooler surfaces of the containment and heats the containment shell. Cooling by the PCS enables continued steam condensation on the shell inner surface and transfer of heat from inside to outside of containment. The condensate flows back to the IRWST.

The PCS provides cooling by a combination of air and water. Water flows on the external top surface and vertical side of the containment steel pressure vessel dome (Fig. 20). The cooling water on the containment shell outer side evaporates and leaves

Fig. 19 AP1000 passive core cooling system (Cummins and Matzie, 2018).

Fig. 20 AP1000 passive containment cooling systems (Cummins and Matzie, 2018).

the shield building with a natural circulation air flow that is induced by the upward steam flow. Air enters the shield building near the top of the cylindrical shield building and flows down an air baffle. The cooling air makes a 180° turn and then flows up between the containment shell and the air baffle. As it flows upward, the air is heated by natural convection heat transfer. The lower density results in an increase in velocity which enables the air to carry the evaporating PCS water upward and out of the shield building roof through a large opening in the center of the roof.

ESBWR passive heat transfer systems

The Economic Simplified Boiling Water Reactor (ESBWR), designed by GE Hitachi Nuclear Energy (2011) and Design Certified by the US NRC, is a Gen III+ reactor with a rated power output in excess of 1500 MWe (Fennern, 2018). Not only does the ESBWR have passive safety systems, but it is also a natural circulation reactor. That is, the ESBWR achieves primary coolant flow without any active coolant circulation pumps. The primary flow is driven by buoyancy differences in the “chimney” region above the core, small pressure differences and jet pumps in the reactor recirculation loops. Fig. 21 illustrates the ESBWR passive safety systems. Most of the passive components in the ESBWR design are employed in other designs that have been built and operated. The ESBWR design is presented herein to illustrate how the systems function.

Normal shutdown cooling at high pressure when the reactor has been isolated from the main steam turbines is done by the Isolation Condenser System. The Isolation Condensers are vertical tube bundles which sit in water compartments outside of containment and at a higher elevation than the RPV. The units are connected to the RPV by a steam inlet line that is always open during operation and a return line that allows for water flow back to the RPV. Upon passive opening of a valve on the return line, the water-filled tubes drain to the RPV and steam is ingested into the top of the tubes. The steam condenses in the tubes and drains by gravity, inducing a natural circulation flow path between the reactor and the condensers.

Low-pressure makeup of reactor coolant inventory is accomplished with the Gravity-Driven Cooling System (GDCS). Three elevated GDCS water pools are located in the containment Drywell. Following a LOCA and depressurization of the primary system, the GDCS pools can drain by gravity into the RPV, providing short-term makeup water. Long-term makeup is enabled by an Equalization Line, a line between the Suppression Pool and the RPV. The Equalization Line allows flow into the primary side from the Suppression Pool due to the hydrodynamic head ($\rho g \Delta H$ term) between the Suppression Pool and the RPV. The much larger Suppression Pool water volume is sufficient to flood the RPV to an elevation well above the core. With adequate coolant inventory, the decay heat is removed by natural convection heat transfer and/or vaporization.

With the core well cooled at low pressure by the GDCS and/or Equalization Line water, containment heat removal is next considered. Under Design Basis Accident conditions, heat released from the primary system to the containment must be removed in order to remain within containment pressure and temperature limits. The Passive Containment Cooling System (PCCS) provides this function by ingesting a steam-noncondensable gas mixture from the containment Drywell and condensing the steam in heat exchangers located outside of containment. These six PCCS heat exchangers are vertical tube bundles located in elevated water compartments outside of containment, similar in design to the IC units. The steam condensed in the PCCS units drains to the GDCS Pools by gravity, and thereafter to the RPV as core makeup. The PCCS units vent noncondensable gases to the Suppression Pool. The pressure difference between the Drywell and the Suppression Pool drives the natural circulation flow through the PCCS.

returns from the condenser to the steam generator (PWR) or RPV (BWR). The processes are further explained in the Temperature-Entropy (T-s) diagram of Fig. 24.

In superheating, a heater is added to heat steam into the superheated region, to the right of the vapor dome on a T-s diagram (Fig. 25). The sensible heat of the steam entering the turbine is increased. The results are drier steam into the turbine and increased work from the turbine, to increase the cycle thermal efficiency. If the system is properly designed, the cost of the superheater is offset by the increased turbine work and thermal efficiency.

With reheating, the fluid is heated again after partial expansion in the turbine (Fig. 26). The steam flowing into the low-pressure turbine is therefore drier and can undergo more expansion in the low-pressure turbine than without reheating. The results are drier steam into the turbine and increased work from the turbine, to increase the cycle thermal efficiency. Similar to superheating, if the system is properly designed, the cost of the superheater is offset by the increased turbine work and thermal efficiency.

As the final Rankine cycle improvement, moisture separation is used to remove moisture from the partially expanded steam before it flows into the low-pressure turbine. The benefit of this process is increased life of the turbine by protecting the turbine blades from impinging water droplets. The thermal efficiency is not increased. Fig. 27 shows the components involved and the T-s diagram (Fig. 27).

An actual nuclear reactor plant uses a combined moisture separator-reheater between the high-pressure and low-pressure turbines to remove moisture from the wet steam exiting the high-pressure turbine and to add superheat to the steam before entering the low-pressure turbine. This configuration is shown in Fig. 22.

The range of thermal efficiency for a commercial nuclear power plant is between 30–38% with these improvements included.

Summary

The basic phenomena occurring in nuclear reactor heat transfer systems were described in this article. Included are heat transfer systems for normal operation, normal shutdown and breach of the primary system, starting with the nuclear fission reactor and extending out to and including the Ultimate Heat Sink. LWR systems were given primary focus, including active and passive reactors and passive safety systems. The intention is to summarize the basic concepts so that the reader is prepared to investigate specific reactor designs of interest in greater detail.

Introduction**Importance of instrumentation and control systems in nuclear power plants**

The instrumentation and control (I&C) systems in a nuclear power plant (NPP), along with their enabling features, serve as the “central nervous system” of a NPP. These systems ensure the safe, reliable, and economic operation of the power plant. The I&C architecture includes plant control, protection, and monitoring systems that provide information to various actuators and devices to ensure the safe and efficient operation of the plant, and to the operation and maintenance (O&M) personnel for making timely decisions. The information about plant parameters and plant status are communicated continuously to various modules in real time so that appropriate actions may be taken by the plant sub-systems.

This chapter focuses on a technical description of the instrumentation and control systems used currently in light water reactor (pressurized water reactor (PWR) and boiling water reactor (BWR)) plants.

Outline of the chapter

The chapter covers the following topics related to nuclear plant I&C.

- Overview of I&C systems
- Instrumentation in light water reactors and heavy water reactors. This addresses field device level technology that is cross cutting elements of I&C, with a limited discussion of actuators
- Control strategies in PWRs and BWRs
- Protection systems with focus on principles such as separation, redundancy, defense-in-depth and diversity
- Digital I&C modernization
- I&C concepts for small modular reactors and advanced reactors
- Summary

Overview of I&C systems

Overall objective of I&C systems

The functions performed by I&C systems in a NPP are threefold.

- The plant measurements are communicated to control, monitoring, and protection systems. The operator or a plant monitoring system uses the sensory information to track the operational behavior of the plant and look for deviations from normal conditions.
- The measurements are used by control systems to regulate the overall plant output and outputs of various plant systems. The goal is to minimize the deviations of important variables from their set points.
- The third function is the actuation of safety systems in case of abnormal deviation from normal plant behavior, some of which may be caused by human operators. Under these situations, the safety systems provide “automatic action to protect the plant and the environment.”

Fig. 1 is a block diagram showing the functional relationship among these three major systems.

Characterization of I&C systems using a functional approach

Plant I&C systems are represented in terms of sensors, data acquisition, display, communication, monitoring, control, and safety systems that are integrated with plant dynamics (reactor power, thermal-hydraulics, energy conversion) and operator interfaces, referred to as human system interface (HSI). Fig. 2 is a schematic of the functional representation of I&C systems in a nuclear plant (IAEA Nuclear Energy Series, 2011). In digital systems, analog outputs from instrument channels are sampled at desired rates to provide the required information that flows to monitoring, control, and safety systems. Actuators are part of the control and safety loops.

The functionality in the I&C system architecture includes the following (IAEA Nuclear Energy Series, 2011): “Data acquisition, actuator activation, signal and command validation, arbitration, control, limitation, checking, monitoring, command, prediction, communication, fault/alarm management, and configuration management.” In the U.S., the safety system design principle follows the IEEE 1E classification. Important elements of the design approach include “functional isolation; redundancy; physical, electrical

Fig. 1 Integration of I&C systems.

and communications isolation; diversity and defense-in-depth; electrical noise emissions and immunity; installation, maintenance and design change control" (IAEA Nuclear Energy Series, 2011).

Characterization of I&C systems using a physical approach

Another description of I&C systems is to present their physical layout, along with sensors and actuators used, and the communication of information among the different sub-systems. This provides a clearer visualization of the functions of the NPP I&C systems compared to a functional description (IAEA Nuclear Energy Series, 2011).

Process interfaces include primarily sensors that measure various process variables, neutron flux, and other parameters. Examples of sensors include temperature, pressure, liquid level, flow rate, neutron flux detectors, radiation monitoring, chemical parameters, position, number of rotations, and shaft speed. Other related devices include signal processing electronics, smart transmitters, trip logic, process sensing lines (such as pressure instrument tubes), and equipment monitoring and diagnostics measurements (such as vibration sensors, ultrasonic transducers, infrared thermography).

There is a multitude of major and minor control loops distributed in the plant. A large number of actuators is used for providing control actions. Examples include motor-operated valves (MOVs), solenoid-operated valves, air-operated valves, switchgears, motor controls, control rod drive mechanisms, heater banks, and water spray systems (pressurizer, core, containment). Communication from the sensors to other parts of the system is achieved by cables carrying both analog and digital signals. HART (Highway Addressable Remote Transducer) protocol and wired digital fieldbus interfaces are common. Digital wireless communication is being considered in many applications.

A digital data acquisition system consists of signal conditioning (filters and amplifiers), analog-to-digital conversion (ADC) device, and data storage. Control systems are either centralized or distributed. In a centralized control system, the processing capabilities and the plant data are at one central location. In a distributed control, these features are distributed or localized throughout the process. In this case, the control actions and the database are available individually throughout the system, with necessary communication among the distributed controllers.

Plant I&C operator support systems include "safety parameter display systems, computerized procedures, I&C system documentation, and process performance monitoring." Different forms of plant simulators are available to operators. These include training simulators, engineering simulators, research simulators, and multifunction simulators. Some of these simulators mimic plant operational transients and accident scenarios.

Instrumentation in nuclear power plants

Introduction

This section presents a summary of instrumentation used in light water reactors (PWRs and BWRs). Kerlin and Upadhyaya (2019) contains a summary of instrumentation systems in pressurized heavy water reactors (PHWRs) and certain advanced reactors. Additional information and details on instrumentation are given in DOE Fundamentals Handbook (1992a,b) and Harrer and Beckerley (1973, 1974).

Instrumentation systems in a large NPP communicate sensor measurements to control, safety, and plant monitoring systems. They consist of process sensors, neutron detectors, radiation monitors, logic devices and other devices, totaling about 10,000 in a large NPP. A factor contributing to this large number is the redundancy in safety system sensors.

Process instrumentation

Process instrumentation in PWRs and BWRs consist of temperature, pressure, flow, and level sensors. The sensors are manufactured and supplied by vendors who specialize in nuclear grade instrumentation.

Temperature sensors

Commonly used temperature instrumentation consists of resistance temperature detectors (RTDs) and thermocouples. RTDs are more accurate for temperature measurement than thermocouples and are used to measure hot leg and cold leg temperatures in a PWR. Thermocouples measure PWR core-exit temperature and other fluid temperatures in a power plant.

Temperature measurement using RTDs is based on the principle that the electrical resistance of a wire changes with temperature. Platinum wire is the common sensing material used in RTDs; its resistance increases almost linearly with temperature. Temperature vs. resistance calibration provides an excellent relationship for accurate temperature measurement. RTDs are installed either by using a thermo-well that makes contact with a fluid in a pipe or in a bypass loop attached to the pipe. The RTD wire is generally wound around a mandrel and is encased in a stainless-steel sheath with an insulating material such as magnesium oxide. The response time of RTDs depends on the RTD sheath thickness and the installation (Kerlin and Shepard, 1982).

Thermocouples are used extensively for fluid temperature measurement in NPPs. They are less expensive and easier to manufacture than RTDs. A thermocouple has two dissimilar wires joined at a junction which is the measuring point. The temperature difference between the junction and the open end of the wire creates a voltage drop. Thermocouple wires are encased in a stainless-steel sheath with an insulating material between the wires and the sheath inner wall (Kerlin and Shepard, 1982). The common thermocouple is of Type-K that uses chromel-alumel wires. For higher temperature measurements Type-N (nicrosil-nisil) thermocouples are used.

Pressure sensors

Pressure sensors used in reactor applications must measure high pressures in the range 50–153 bars (≈ 750 –2250 lbf/in²). The devices must be able to withstand high temperatures and radioactive environment. The most common pressure sensor has a metallic diaphragm that moves (expansion and contraction) when a pressure is applied (DOE Fundamentals Handbook, 1992a). This movement can be measured electronically using changes in capacitance between two plates. Pressure sensors measure both absolute pressure and differential pressure.

New piezo-electric pressure sensors are being developed. The applicability of these sensors is limited by the temperature of the medium. The piezo-electric property is effective up to a temperature of about 300 °C. Artificial piezo materials are common in these applications. An example is the material lead-zirconate-titanate (PZT) which has a Curie temperature higher than natural crystals.

Flow sensors

The common flow measurement technique in light water reactors is based on measuring pressure drop across an orifice meter or a venturi meter. The pressure drop, Δp , is measured by a differential pressure transmitter. The flow velocity is proportional to $\sqrt{\Delta p}$. The volumetric flow rate is calculated knowing the cross-sectional areas at the pipe and the constriction, and the pressure drop. Since a bend in a pipe would also result in a pressure drop, flow velocity can also be estimated by measuring this pressure drop and the knowledge of the pipe diameter.

Ultrasonic flow meters are used extensively for monitoring liquid flow rate in industrial processes. An advantage of the ultrasonic flow meter is that it is not necessary to expose the device directly in the flow regime. The principle of reflection transit time ultrasonic flow meter (Lish et al., 2017) can be adapted to measurement in a reactor plenum, such as in the downcomer region. Two ultrasonic transducers are installed outside the pipe or plenum on the same side at a known distance apart. Each device acts as a transducer and a receiver. An ultrasonic wave is pulsed from the transducer in the direction of flow (downstream) to strike an opposite surface. The reflected wave is then received by the downstream transducer. The total time of transit is recorded (t_d). In a similar fashion, a wave is pulsed in the direction opposite to the flow (upstream). The reflected wave is received at the upstream transducer. This total time of transit is recorded (t_u). Because of the manner in which the two pulses are transmitted, $t_u > t_d$. Knowing these two transit times and the angle of incident of the ultrasonic pulses on the opposite surface, and the distance between the detectors, we can calculate the average flow velocity (Lish et al., 2017). This approach is well-suited for integral small reactors where the space available for sensor placement is limited. Light-water small modular reactors have no primary piping,

and direct measurement of primary coolant flow rate is challenging. A similar challenge is presented by BWRs with internal pumps, or natural circulation.

For flow measurement in liquid metal reactors (such as the sodium fast reactor), magnetic and eddy current flow meters are good candidates (Vaidyanathan et al., 2012).

The above flow measurement techniques require physical placement of sensors. An alternate approach for flow velocity measurement uses cross correlation between two signals from sensors that are installed to measure either temperatures or in-core neutron flux. This is the case with in-core neutron detector strings in BWRs or in-core SPND (self-powered neutron detector) strings used in PWRs. As the water (single or two-phase) flows by these detectors, the neutron detection gets affected and generates fluctuations that can be detected at two adjacent detectors. A cross-correlation function between the detector signals may be used to estimate the transit delay time, which is the correlation lag where the cross correlation has a maximum value (Sweeney et al., 1985).

Nitrogen-16 (N-16) detectors are used for monitoring primary coolant flow rate in PWRs. Cross correlation between adjacent N-16 detectors is used to estimate the flow transit time, and the average coolant velocity. See section “**Instrumentation in pressurized water reactors**” for details. The use of diverse measurement methods would complement each other and provide reliable measurements of flow rates.

Level sensors

The differential pressure between two points, above and below the water column in a vessel, is proportional to the height of the water column, as shown in Eq. (1).

$$p = \rho gh \quad (1)$$

p = differential pressure; ρ = density of water; g = acceleration due to gravity; h = height of the water column.

This relationship is used to make level measurements in light water reactors. This requires the knowledge of liquid density at a given temperature. Examples of such measurements are: downcomer level in a U-tube steam generator (water level above the U-tubes), pressurizer water level, and water level in a BWR vessel.

The section on “**Control of PWRs and BWRs**” describes the regulation of vessel liquid levels at desired set point values.

Another approach for level measurement is the use of time of flight instruments. The time of flight measurement may be made either by using ultrasonic pulses or high frequency guided radio waves. Ultrasonic waves are transmitted from a piezo-electric transducer towards the liquid. The ultrasonic pulse strikes the liquid level and reflects back (because of a change in the density of the two media), and the reflected wave is received by the pulse-echo device. Knowing the time of flight and the velocity of sound in the medium above the liquid level, the distance between the transducer and the liquid level is calculated.

Guided wave radar (GWR) is another technology for level measurement (Endress and Hauser, 2020). In this approach a high frequency radio wave is passed through a waveguide which extends into the liquid. When the wave hits the liquid surface, it gets reflected through the waveguide back to the receiver. By measuring the time of flight, an estimate of the distance between the probe and the liquid level is made. This technique needs further development and demonstration for reactor applications.

Neutron detectors

The measurement of nuclear power is made using neutron detectors. Neutron flux, is defined as the number of neutrons/cm²-sec. A typical value of thermal neutron flux in a PWR at full power is in the range 10¹³–10¹⁵ neutrons/cm²-sec. Neutron flux is the product of neutron density and the average velocity of neutrons at a certain energy level. The reactor power is proportional to core average neutron flux. The estimation of reactor thermal power is outlined in sections “**Major control systems in a PWR**” and “**Control of boiling water reactors**”.

The flux measurement is made during reactor start-up, intermediate power range, and power operation. Different detectors are being used depending on the reactor operation regime.

Fission chambers

Fission chambers are used during reactor start-up to measure low flux and can cover an extended range of reactor operating conditions. The inside of a fission chamber is coated with a thin layer of highly enriched U-235 and filled with oxygen-free argon gas. The fission caused by the interaction of neutrons with the coating results in high energy fragments (fission products) that ionize the argon gas and produce a current that is measured, either in the pulse mode or in the current mode (Campbell mode). The charge pulses generated by neutron capture are much greater than the pulses generated by gamma capture. Consequently, the measurement content arising from the fission flux is much greater than the gamma-ray flux, even at start-up and low-power conditions. Thus, fission chamber measurement overlaps both the source range and power range modes. Fission chambers are used both in PWRs and in BWRs.

Ionization chambers

Ionization chambers are neutron detectors with a neutron absorbing material that is filled into the chamber as a gas with the central element acting as anode and the chamber wall as cathode. The chamber is filled with BF₃ gas. Boron-10 has a high thermal neutron absorption cross section. A neutron absorption in B-10 produces two charged particles—Li-7 and α -particle (see Eq. 2), and the

resulting current is measured. The sensitivity to gamma energy can be reduced by proper design of the chamber, often referred to as compensated ion chamber.

Compensated ionization chambers are suitable for measuring flux in the range 10^4 – 10^{12} neutrons/cm²-sec, and are used in the intermediate power range mode.

Self-powered neutron detectors (SPNDs)

These detectors are used for measurement of localized neutron flux. These are generally configured as in-core neutron detector strings with four detectors placed along each instrument tube. A thermocouple is installed at the tip of the instrument tube for core-exit temperature monitoring in PWRs. SPNDs consist of a neutron absorbing material such as Vanadium, Rhodium, Cadmium or Cobalt inside a stainless-steel sheath. SPNDs consist of an emitter, insulation, and a collector (sheath). The neutron activation of the emitter material produces beta decay, and the resulting electrons migrate towards the collector and a current is measured. The current level is very low and requires amplification for proper data acquisition.

SPNDs are slow responding detectors because of the large half-life of the beta emitter material. These detectors remain calibrated longer than fission and ionization chambers. They are well-suited for in-core monitoring and flux mapping.

Instrumentation in pressurized water reactors

Fig. 3 is a schematic of a PWR plant showing the major sensors and their placement on the primary and secondary sides of the plant (Kerlin and Upadhyaya, 2019).

Following are the process and neutron flux instrumentation in a PWR. See Fig. 3.

- Hot leg and cold leg RTDs. These are used in control and safety system functions.
- Pressurizer pressure (primary pressure) and pressurizer water level.
- Primary coolant flow rate.
- Steam generator feedwater flow rate, steam flow rate, downcomer level (in U-tube steam generators).
- Core-exit thermocouples (Type-K) to measure the coolant temperature at ≈ 45 locations. The thermocouples are introduced through conduits at the vessel head ports.
- Digital rod position indicator signal.
- Traversing in-core probes (TIP) are used to perform three-dimensional flux mapping. The TIP detectors are small fission chambers that are introduced by a drive system through instrument thimble guides that extend through the entire length of the core. Fig. 4 shows the arrangement of in-core instrumentation in a Westinghouse PWR (Westinghouse Electric Company, 1984).
- Ex-vessel neutron detectors are used for power monitoring from start-up to full power operation. Two source range detectors (fission chambers) and two intermediate range neutron detectors (compensated ionization chambers) are placed in the biological shield surrounding the reactor vessel. Two sets of four ionization chambers (BF_3 -filled) measure the neutron flux in the upper half and in the lower half of the core. These long detector chambers are placed symmetrically between each pair of hot leg

Fig. 3 Important plant instrumentation of a PWR with U-tube steam generators. Kerlin TW and Upadhyaya BR (2019) *Dynamics and Control of Nuclear Reactors*. Cambridge, MA: Elsevier—Academic Press.

and cold leg pipe nozzles as shown in Fig. 5. Four current signals are calculated by adding the outputs of a pair of corresponding upper and lower detector currents and provide information about any power offset. The power range detectors measure up to 120% of full power.

- Nitrogen-16 (N-16) detector monitors the thermal power of the NSSS by measuring the level of N-16 present in the coolant due to a neutron reaction with the O-16. The decay of N-16 isotope produces high energy gamma rays that are measured by ionization chambers placed on hot leg piping close to the reactor vessel (Westinghouse Electric Company, 1984). The N-16 fluctuations may be measured by gamma detectors at two locations in the pipe to estimate the transit time. Cross correlation between the two detector signals is used to estimate the transit time. Knowing the distance between the detectors, the transit time of N-16 activity, and the pipe inside area, the volumetric flow rate of the primary coolant is estimated. This parameter complements flow rate measurement using standard flow meters.

Instrumentation in boiling water reactors

Instrumentation requirement in a BWR is somewhat different compared to that for a PWR. This is primarily due to the differences in the NSSS and the reactor control strategy. The following are the typical measurements in a BWR (Kerlin and Upadhyaya, 2019).

- Reactor coolant flow rate. This is measured by venturi meters at the recirculation pump discharge locations. There are two recirculation pumps in a BWR-6 plant that supply water to a set of jet pumps.
- Reactor vessel water level.
- Steam flow rate.
- Reactor pressure (steam pressure).
- Feed water flow rate.
- Feed water temperature.
- Local power range monitors (LPRMs). An LPRM detector tube has four fission chambers, placed 36-in. apart, with the bottom and top detectors 18-in. from the top and bottom of core.
- Average power range monitor (APRM) signal is an average of about 20 LPRM detector signals from across the core. The APRM signal provides the global core power behavior.

A large BWR core (1220 MWe) has approximately 45 LPRM detector tube locations. Each detector tube is placed among four fuel channels, with the central tubular space available for a TIP detector. The TIP detector is used for calibrating the LPRM fission

Fig. 5 Locations of four ex-vessel ionization chambers in a PWR, numbered I, II, III and IV. Detectors I & II and III & IV are placed diametrically opposite to each other. Figure shows the reactor core, core support barrel, pressure vessel, hot leg and cold leg nozzles in a four-loop plant. chambers. **Fig. 6** shows a BWR core map. The detector locations are shown as dark circles and the crosses (+) indicate control assembly locations (Fry et al., 1984).

Actuators

A nuclear power plant has a large number of control loops performing major control actions centrally and minor control actions in a distributed architecture. Effective process regulation requires reliable actuators. Examples of some of the actuators are MOVs, solenoid-operated valves, air-operated valves, switchgears, motor controls, control rod drive mechanisms, heater banks, and spray systems. These actuations result in changes in flow rate, liquid level, temperature, pressure, nuclear reactions and others.

In all these situations it is not only necessary to provide the right command signal but also to monitor the amount of actuation performed by the devices. Examples are valve position, control rod position, switch positions, power on-off condition, etc. Actuators are used in control and safety systems of a NPP.

Remarks

See Garland (2019) for details of instrumentation in the CANDU reactor. Vaidyanathan et al. (2012) describe instrumentation in sodium fast reactors. See Kerlin and Upadhyaya (2019) for a summary of instrumentation in high temperature gas-cooled reactors and molten salt reactors.

Control of PWRs and BWRs

Introduction

Control systems have two objectives: (1) to move the process from one set point to another set point as quickly as possible without compromising safety and exceeding process parameter limits; (2) to regulate the process at a desired operating condition by overcoming the undesirable effects of external and internal disturbances.

Fig. 6 BWR core map showing LPRM detector string locations. Detector locations are indicated by dark circles and control assemblies by crosses (+). Fry DN, March-Leuba J and Sweeney FJ (1984) Use of Neutron Noise for Diagnosis of In-Vessel Anomalies in Light Water Reactors. ORNL/TM-8774.

The primary control objective in a nuclear power plant is to regulate the plant output at a desired power level. In some situations, it may be necessary to maneuver the plant to follow a variable load demand. The control actions result in changes in process parameters. The control strategy should maintain the plant in a safe mode and ensure that all parameters are within safe limits. Because of coupling among plant systems, control maneuver in one system would result in the activation of other control loops. Most control strategies are of the closed-loop type. The following topics are presented in this section:

- Basic control actions
- Control strategy in PWRs with U-tube and once-through steam generators
- Control strategy in BWRs and impact of BWR evolution.

Control actions

Simple controllers

Most industrial control systems are of the closed-loop type. In an open-loop controller, the system input or perturbation is not affected directly by its output. An implicit calibration between the input and the output exists, such as in opening and closing a water tap to achieve a desired flow rate. In a closed-loop control system, the output is compared with its set point value, and the control action (actuation) is applied to minimize the error between the set point and the measured output. The error signal, $e(t)$, is given by.

Error signal, $e = \text{Set point, } X_{set} - \text{Measurement, } X_m$

$$e(t) = X_{set}(t) - X_m(t) \quad (3)$$

Simple control actions are on-off and proportional controllers. These control actions are enhanced by using a dead band, such that the control action does not change (or remains the same) when the error falls in a pre-defined error band.

Proportional-integral-differential controllers

The error signal using a proportional controller remains non-zero at steady-state conditions. This can be overcome by adding a control action that depends on continuous integration of the error. Such controllers are called integral controllers. A proportional-integral (PI) controller has the form

$$f(t) = K_p e(t) + K_i \int_0^t e(r) dr \quad (4)$$

$f(t)$ = control action; K_p = proportional constant; K_i = integral constant.

In some dynamics, where there is a delay between the control action and the system response, the system dynamics may become unstable because of the time mismatch between error signal and the control actuation. This issue may be resolved by using differential control action in the form

$$f_D(t) = K_d \left(\frac{de}{dt} \right) \quad (5)$$

This control action has an anticipatory effect on the behavior of the error signal. In general, a combination of the three control actions may be used as shown in Eq. (6).

$$f(t) = K_p e(t) + K_i \int_0^t e(r) dr + K_d \left(\frac{de}{dt} \right) \quad (6)$$

This control design is referred to as a proportional-integral-differential (PID) controller. Some experimentation is necessary for choosing the PID parameters K_p , K_i , and K_d . Differentiating an error signal may result in jumps (due to noise) in the parameter (de/dt) , and thus cause unnecessary variations in the control signal $f(t)$. This is avoided by filtering the error signal $e(t)$ and then performing the differentiation. PID controllers are the most used control strategies presently in the process and power industries.

Major control systems in a PWR

The following are the important control loops in a PWR:

- Reactor power control through reactivity insertion by control rod actuation.
- Primary loop pressure control using spray systems and heater banks in the pressurizer.
- Pressurizer water level control using CVCS flow perturbation either to increase or to decrease the level to the set point.
- Steam generator level control in a U-tube steam generator using feedwater flow perturbation.
- Steam generator pressure control in a once-through steam generator by varying feedwater flow demand that changes as the steam flow demand to the turbine changes.
- Turbine power by actuating turbine control valve either to match power set point or to regulate steam pressure set point.

These control strategies are presented for PWRs with U-tube steam generators (UTSGs) and once-through steam generators (OTSGs).

Steady-state temperature program in a PWR with UTSGs

The purpose of the reactor power control system in a PWR is to respond to the changes in the load demand and to regulate the power at a given steady-state condition. Sudden changes in the turbine demand can be handled without scrambling the reactor, by bypassing the steam. Automatic control is employed for power levels above approximately 20%. The set points of the control system are based on the desired power level. Such a procedure is called a steady-state program.

Consider steady-state conditions. The heat balance on the primary side is given by

$$P_R = WC_p (T_{HL} - T_{CL}) \quad (7)$$

P_R = reactor power; W = total core coolant mass flow rate; C_p = specific heat capacity of coolant; T_{HL} = average hot leg temperature; T_{CL} = average cold leg temperature.

The power delivered to the secondary side, P_s , is given by

$$P_s = (h_{eff} A)_{SG} (T_{avg} - T_s) \quad (8)$$

h_{eff} = average effective primary-to-secondary heat transfer coefficient for the steam generator; A = total heat transfer area in the steam generator; $T_{avg} = \frac{T_{HL} + T_{CL}}{2}$, average primary coolant temperature; T_s = average temperature of the secondary fluid, which is at saturated condition in most of the shell-side volume.

Eq. (7) indicates that, for a fixed coolant flow rate, $(T_{HL} - T_{CL})$ increases with reactor power. From Eq. (8), the power delivered to the secondary side can be affected by the three parameters $(h_{eff} A)_{SG}$, T_{avg} and T_s . It is desired to maintain almost constant steam temperature T_s in order to minimize the duty on the turbine. This requires that either $(h_{eff} A)_{SG}$ or T_{avg} , or both change with the power level. Also note that Eqs. (7) and (8) do not require that the cold leg temperature T_{CL} be constant, increasing, or decreasing. The variations in T_{CL} and T_s depend on the type of steam generator, and in general these temperatures adjust to the desired steady-

state conditions. That is, T_{CL} and T_s are not directly controlled. The steam generator pressure remains at approximately constant value due to the manipulation of the turbine control valve as the turbine demand changes and the steam production changes accordingly. In a UTSG, $(h_{eff}A)_{SG}$ remains approximately constant. But, T_{HL} increases with power, its rate of change being set by the power level. Thus, the quantity that changes in order to deliver necessary secondary power is the average primary coolant temperature, T_{avg} . The programmed change in T_{avg} as a function of turbine load (power) is called the T -average program, or the steady-state temperature program.

The following is the sequence of actions during a load-following maneuver: the case of load change from 80% to 100%. Control in the range 0–20% power is primarily manual.

- The action by the operator creates an error signal between the desired turbine load and the actual turbine output. The turbine header pressure (inlet pressure to the turbine) is directly correlated to turbine output.
- The error signal goes to the turbine control valve (TCV) which is manipulated to minimize the error. For an increase in the turbine load demand, the error increases causing the TCV to open.
- The mismatch between the turbine power and the actual measured reactor power initiates a signal to move the control rods, causing an increase in the reactor power. This may be considered as a feed-forward control action. The control action uses the rate of power mismatch. If the power mismatch rate is zero, then this error signal is not utilized by the controller. Also, the gain (or the rate constant) may be changed, a larger value for a larger rate of change of power mismatch, thus providing a quicker action during power maneuvers. This variable gain is sometime called a non-linear gain action.
- The $\{T_{avg}(\text{ref}) - T_{avg}(\text{actual})\}$ error is generated based on the actual turbine output. The turbine output is used for calculating the percent power in the T_{avg} – Power program.
- As the error between the reference T_{avg} and measured T_{avg} increases, the control rods move to increase the reactor power. The total error signal to the control rod drives is a combination of power mismatch signal and the $\{T_{avg}(\text{ref}) - T_{avg}(\text{actual})\}$ error signal.
- The three-element controller generates a signal to feed control valve (FCV) to supply desired feed water rate, and in turn regulate the water level in the steam generator (above the tube bundle). The feed pumps are variable speed, and the pump control tries to maintain constant pressure drop across the FCV.
- There is a pressurizer level versus reactor power program that defines the pressurizer level. Depending on the level mismatch, the charging or the let-down flow changes.
- As the reactor power increases, the measured T_{avg} increases. The control rod motion stops once $\{T_{avg}(\text{ref}) - T_{avg}(\text{actual})\}$ is within a specified dead band.
- The TCV actuation ceases when the desired turbine load matches the calculated turbine output.

Fig. 7 shows the programmed T_{avg} used in a PWR with UTSG, similar to that in a 1100 MWe Westinghouse plant (Kerlin and Upadhyaya, 2019). A PWR with UTSGs operates in the reactor-follow-turbine mode.

Full-length control rods are used for power control. These are divided into four banks A, B, C, D and are moved according to a pre-specified program during start-up. During transient operation, both power mismatch (converted to a temperature scale) and T_{avg} mismatch are used as error signals to determine the rod speed. During steady-state regulation only T_{avg} signal is used for control.

The full-length control rod clusters are operated by a magnetic jack mechanism. The part length rods are manually operated and are used for power shaping purpose. The control rod program is shown in Fig. 8. The rod motion has a dead band of ± 1.5 °F. The rod motion goes to zero for errors in the range ± 1.0 °F. The dead band includes a 0.5 °F lock-up. This avoids a continuous chatter in the control rod motion due to small errors when near a 1 °F temperature mismatch signal, thus ensuring mechanical integrity of the actuator.

Feedwater control in a PWR with UTSGs

The purpose of feedwater regulation in a UTSG or a recirculation type steam generator is to control the flow of water to the steam generator in order to maintain the level of water in the downcomer (the level of water above the top of the tube assemblies).

A mixture of saturated water and steam is generated in a UTSG and flows to the top of the steam generator where the water is separated from the mixture in the steam separators and passes through steam driers before entering the turbine. The separated water flows back to the downcomer region.

Consider the situation when the steam pressure is initially decreased because of increased flow rate to the turbine due to valve opening. This decrease in the pressure causes flashing of the water and as the saturated mixture flows to the steam separators, more water gets recirculated, and flows into the downcomer region. This causes a temporary increase in the water level. This effect is called the *swell phenomenon*. As a result the controller tries to bring the level back to the set point by decreasing the feed flow rate, even though more steam is taken out of the generator. There should be an increase in the feed flow rate. When there is a reduction in the steam flow rate, the opposite happens and there is a shrink in the water level, or the occurrence of a shrink phenomenon. This behavior in a UTSG is called the *shrink-and-swell* phenomenon, resulting in a change in the water level (initially) opposite to the real situation, thus prompting the controller to apply a wrong control action.

For this reason, the control system uses two error signals—mismatch in the steam and feed flow rates and mismatch in the level set point and the measured level. The sum of the water level error signal and the steam flow-feed water flow rate error signal is used to increase or decrease the feed water flow rate to the steam generator. Fig. 9 shows the block diagram of the three-element controller (Kerlin and Upadhyaya, 2019). It is called a three-element controller because three signals are used by the controller to determine the feed flow rate. These are water level, steam flow rate and feed water flow rate.

The error term that is used in the three-element controller to control the feed flow, is a combination of level signal error and the mismatch between steam flow rate and feed flow rate.

Level error, $\Delta L = \text{SG level set point} - \text{SG measured level signal}$

Flow error, $\Delta W = \text{Steam flow rate} - \text{Feed water flow rate}$

Fig. 9 Three-element controller for a U-tube steam generator level control. Kerlin TW and Upadhyaya BR (2019) *Dynamics and Control of Nuclear Reactors*. Cambridge, MA: Elsevier—Academic Press.

Since the flow error and the level error have different physical units, the errors are normalized by the corresponding nominal ranges of these variables. The total error signal feeds into a PI controller that generates a perturbation signal to actuate the feed flow valve. Note that there is no controller for regulating the steam pressure in the UTSG. The change in the steam flow rate (through the TCV) and the resulting change in the feed flow rate determines the steam pressure.

Steady-state temperature program in a PWR with OTSGs

Unlike in UTSGs, the overall heat transfer coefficient from the primary to the secondary fluid in an OTSG changes with power level. The boiling length increases as the power increases to generate more steam, and the portion of the tube surface available for heat transfer in the superheated region decreases. The steam temperature initially follows the hot leg temperature, and then starts to decrease with increasing power.

Referring to Eq. (8), repeated below, since the overall primary-to-secondary heat transfer coefficient increases (with reduced superheat) and the steam temperature decreases with power, a PWR with OTSGs can be operated with a constant T_{avg} program in most of the power range (15–100%). It is necessary to maintain proper water level in the steam generator at low power levels.

$$P_s = (h_{eff}A)_{SG}(T_{avg} - T_s) \quad (8)$$

Because of the increasing boiling with increasing power level, the cold leg temperature decreases with power. Fig. 10 shows the steady-state temperature program for a PWR with OTSGs, such as in Babcock & Wilcox (B&W) PWRs.

Fig. 10 Steady-state temperature program for a PWR with OTSGs. Kerlin TW and Upadhyaya BR (2019) *Dynamics and Control of Nuclear Reactors*. Cambridge, MA: Elsevier—Academic Press.

Feedwater control in a PWR with OTSGs

The control strategy of PWRs with OTSGs is different from PWRs with UTSGs. The OTSG generates superheated steam; the downcomer level is not constant because of changing boiling length. The feedwater flow rate must match the steam flow rate. The feed flow rate increases with the power level (turbine demand) and changes according to a feed flow rate—power program. The steam pressure is regulated at a set point by actuating the steam valve. For example, as the steam production rate increases the steam pressure increases, and more steam is let out of the steam generator, thus bringing the pressure back to its set point. PWRs with OTSGs operate in a turbine-follow-reactor mode.

Turbine control

In PWRs with UTSGs, the TCV responds to a turbine demand and actuates the valve to regulate the steam flow until the mismatch between the turbine demand and actual turbine power is minimized. In PWRs with OTSGs, a change in the steam generation results in a change in the steam pressure. The TCV actuates to change the flow rate so that the steam pressure settles at its set point.

Primary pressure control in a PWR

The primary pressure in a PWR is regulated by a pressurizer which is connected to one of the hot legs using a surge line. The pressurizer contains water and steam, with 60% of the volume filled with water at 100% power. The pressurizer is the only component in the primary system that contains vapor and a free liquid surface. The overall height of the pressurizer in a four-loop plant is ≈ 16.1 m with a diameter of 2.3 m, and a total volume of 31 m^3 . The pressurizer pressure is controlled by electric heaters and a spray device. The bank of heaters has a total power of 1800 kw. The spray device receives water supply from one of the cold legs and has a maximum flow rate of 57 L/s, with a minimum continuous water injection at 63 mL/s.

The nominal primary coolant pressure is 2250 lbf/in^2 (≈ 153 bars). The primary pressure (pressurizer pressure) is regulated using the heater banks and the spray device, respectively to increase or decrease the pressure. There is a combination of on-off and proportional heaters that are actuated as a function of pressure set point error. The spray flow rate is proportional as a function of the pressure set point error. The water level changes due to the change in the hot leg temperature. The water inventory in the pressurizer vessel is controlled by charging and let-down flows provided by the chemical and volume control system (CVCS).

Control of boiling water reactors

The dynamics of boiling water reactors is different from those of PWRs because of the two-phase fluid in the reactor vessel. This affects the core reactivity due to changes in the two-phase fluid density changes (also called void reactivity). This dynamics is unique to BWRs and must be taken into account during reactor start-up, load-following, and steam pressure regulation.

A BWR has the following three major control systems:

- Reactor power control
- Reactor vessel water level control
- Steam pressure control.

BWR power control

The power generation and control in a BWR is achieved by a combination of control rod reactivity and recirculation flow rate. During start-up, criticality is achieved by control rod withdrawal up to about 30% power, with natural circulation providing core flow. Beyond this and up to about 65% power, a combination of control rod withdrawal and increased recirculation flow rate (to achieve a core flow rate of $\approx 40\%$). The control rod actuation ensures that the power reaches the power trajectory line

referred to as the “100% line.” Beyond this point in the power-flow map, reactor power is increased to 100% by increasing the recirculation flow to achieve a core flow rate 100%. Recirculation flow is also used for load-following in the 75–100% power range. It is important to avoid instability in BWR operation with low flow-to-power ratio up to about 30% power. BWRs operate in a turbine-follow-reactor mode, ensuring that enough core flow is available as the reactor power is steadily increased.

The steady-state thermal power generated in a BWR is calculated using the following equation.

$$P_R = W_{ST}(h_{ST} - h_{FW}) \quad (9)$$

P_R = reactor power; W_{ST} = flow rate of steam exiting the reactor vessel; h_{ST} = enthalpy of steam at the exit quality; h_{FW} = enthalpy of feedwater at the water inlet temperature.

Any vessel heat loss to environment should be added to Eq. (9) in estimating the total reactor power. Accurate measurements of reactor pressure, steam flow rate, and feedwater temperature are important for minimizing the error in calculating the total reactor power generated.

Reactor vessel water level control

The water level in the reactor vessel is maintained at a set point value above the active core. This is similar to the downcomer level control in a UTSG. A three-element controller, using measurements of vessel water level, feedwater flow rate, and steam flow rate, is implemented to ensure enough flow is supplied to the vessel. This controller responds to the “shrink-and-swell” phenomenon, similar to that in a UTSG dynamics. As the water level is restored to its set point, the mismatch between the steam flow and feedwater flow is minimized.

Steam pressure control

As the reactor power increases to respond to a change in the power demand, steam generation increases, causing an increase in steam pressure. This sends a signal to the TCV actuation to increase the valve opening, thus increasing the steam flow rate and reducing the pressure back to the set point. The TCV actuation ceases when the steam pressure reaches the set point.

Consider a load-following operation to increase the power from 80% to 100%. The recirculation flow increases to a predetermined value, thus increasing the core flow. The increased coolant flow reduces coolant void fraction which increases core reactivity causing an increase in reactor power, and in turn increased steam production. This results in an increase in the steam pressure that sends a signal to the TCV to increase the valve opening. This increases the steam flow to the turbine and decreases the steam pressure. The valve actuation ceases when the steam pressure settles to its set point value. At the same time, the feedwater valve actuation increases the feedwater flow rate to regulate the vessel water level. This sequence of control actions in a BWR is similar to the turbine-follow-reactor operation. Control action is also initiated if there is a mismatch between generator frequency and grid frequency (GE Hitachi Nuclear Energy, 1972).

Safety systems

Introduction

Safety systems in a nuclear power plant are designed to sense abnormal occurrences and/or accidents in the reactor and to initiate automatic actions to place the plant in a safe condition. The primary purpose of safety systems is to protect the physical barriers that contain radioactive fission products in the reactor core and, thereby, prevent exposure of the general public. Safety systems have two objectives: (1) terminate the nuclear chain reaction and (2) remove residual thermal energy from the core. The first objective is accomplished through a reactor protection or trip system, which rapidly inserts safety assemblies of neutron absorber material into the core to “starve” the fission chain reactions and end the sustained nuclear generation of thermal power. The second objective is accomplished through actuation of engineered safety features to remove residual heat from the core arising from fission product decay. These protective I&C systems, reactor trip system (RTS) and engineered safety features actuation system (ESFAS), act automatically when design basis event conditions are detected to ensure avoidance of excessive energy buildup (heat and pressure) that could compromise the protective barriers.

Safety system architectures

Safety systems are typically implemented in redundant configurations consisting of (1) sense and command divisions for detecting events and determining when a safety action is required and (2) execute trains for coincidence logic voting on the safety commands issued by the sense and command divisions and then actuating a safety response when required. These safety I&C architectures generally provide instrumentation channels for each protective function within the redundant divisions, feeding voting structures for actuation signaling within a one-out-of-two equipment train scheme. The approach to implementing safety functions is for the sense and command divisions to compare critical plant parameters to trip set points associated with postulated initiating events and for the execute trains to initiate protective action based on coincident occurrence of trip set points being exceeded. The sense and command divisions consist of independent sensors and electronics while the execute trains consist of independent voting arrays (e.g., relays, breakers) and actuators (e.g., control rod drive mechanisms, valves, pumps). The voting scheme for PWRs and advanced BWRs is typically two-out-of-four (or 2oo4) general coincidence among the trip/no-trip outputs from the sense and command

redundancies. The traditional voting scheme for BWRs is one-out-of-two taken twice (i.e., at least one of two redundancies in each train indicating trip conditions).

Reactor trip system

The RTS initiates a reactor trip or scram to prevent the reactor from operating in a condition that could cause damage to the core. The tripped state is achieved by the rapid insertion of safety assemblies (e.g., rods or blades). For PWRs, this is accomplished by de-energizing the electromagnetic coupling of the safety rods to the control rod drive mechanism, which causes the rods to drop into the core from above. For BWRs, this is accomplished by de-energizing relays that release pressurized gas from accumulators to hydraulically push the safety blades into the core from below. In each case, the trip action stops the nuclear chain reactor and thereby limits peak fuel centerline and cladding temperatures along with coolant system temperatures and pressures. The RTS along with safety relief valves and the ESFAS constitute the reactor protection system.

Engineered safety features actuation system

Upon detection of accident conditions, the ESFAS actuates or realigns safety-related systems and equipment assigned to engineered safety feature functions to ensure that accident consequences are kept within acceptable limits. These features include emergency core cooling systems, residual heat removal systems, and isolation valves. Additionally, BWRs provide the Standby Liquid Control System to inject negative reactivity through liquid chemical control as an alternate to reactor trip by control element insertion. This feature serves to address anticipated transient without scram (ATWS) scenarios. PWRs also provide ATWS functions to enable diverse automatic means of initiating rod drop.

Digital I&C modernization

Introduction

The benefits of digital technology include the following ([IAEA Nuclear Energy Series, 2011](#)): improved accuracy of instrument and controller outputs; absence of drifts in electronic component; ease of implementing complex mathematical functions; capability for high-capacity data capture, information extraction, and integrated O&M actions and activities; on-line monitoring, diagnostics, and fault correction; self-diagnostics of instrumentation and protection systems; and improved human system interaction. The deployment of digital I&C technology can enhance plant safety and economic benefits. Additionally, analog equipment is becoming more difficult to acquire in a marketplace dominated by the process industry, which has embraced the benefits and flexibility of digital technology. The increasing obsolescence of analog I&C technology for power plants hampers the nuclear power industry, but regulatory uncertainty constrains the transition to digital. Modernization of I&C systems at NPPs requires special treatment of the characteristics of digital technology and the focused enforcement of key safety principles ([Upadhyaya et al., 2013](#); [IAEA Nuclear Energy Series, 2015](#)).

Characteristics of a digital I&C system

The fundamental difference between analog and digital I&C systems relates to the way plant signals/data are acquired and processed functionally. In a digital I&C system, the signals from various sensors and devices are sampled at a specified rate (for example, samples/s) and the digitized data are transmitted to processing modules to provide desired outputs for use by other plant systems and personnel. The nature of digital systems tends towards aggregated functions that are executed sequentially in software code using data “snapshots.” Conversely, an “analog I&C system responds to instantaneous values of continuously varying signals, and the information is propagated and processed in parallel as part of separate functions embodied in discrete, dedicated components” ([IAEA Nuclear Energy Series, 2011](#)). Despite the identified benefits of the technology, the capabilities and characteristics it provides also pose challenges to developing a safety justification for implementing protection functions in digital systems. For example, the integration of function in fewer devices, time-sequence dependence of data and computation, and the abstraction of functionality in software versus analog physical processes can result in complex systems that are difficult to analyze, too complex to model, and subject to an untestable number of potential states. Consequently, the nuclear power industry employs rigorous quality assurance and qualification processes throughout a digital system’s lifecycle.

Safety principles for digital I&C systems

I&C systems at NPPs adhere to safety principles that originated and evolved from the outset of reactor development. The most fundamental principle is defense-in-depth. The general design criteria (GDC) provided in Appendix A of Title 10, Part 50 of the Code of Federal Regulations (10 CFR 50) establish the minimum design requirements for light-water reactors. These design criteria embody principles such as high quality, integrity, reliability, independence, and qualification. Independence and redundancy, as well as physical barriers and electrical isolation, are generally applied as design measures to address potential vulnerabilities related

to a single failure of equipment and the propagation of failure effects. Diversity is the prevalent means of addressing common-cause failure (CCF).

The U.S. Nuclear Regulatory Commission (NRC) and digital I&C vendors have identified several issues associated with the application of digital technology that must be addressed in the *design, licensing, installation, and operation of a digital safety system* (Upadhyaya et al., 2013; IAEA Nuclear Energy Series, 2015; National Research Council, 1997). The primary safety principles that involve unique considerations for digital I&C systems are.

- Diversity and defense-in-depth (D3)
- Quality assurance
- Cyber security

Diversity and defense-in-depth (D3)

Defense-in-depth (DiD) is a fundamental safety principle for the design, construction, and operation of nuclear reactors with a substantial historical basis. It can be described in terms of a concentric arrangement of protective barriers to ensure public health and safety. Before any harmful radiological release can occur to adversely affect the public or the environment, all of the barriers (i.e., fuel rod cladding, reactor coolant system pressure boundary, containment, and emergency response) must be breached. I&C systems have an important role in maintaining the integrity of these barriers. The DiD principle, as applied to I&C systems, was advanced mainly in response to the anticipation that degradation may not be wholly predictable, and that safety can be best assured by multiple independent lines (or echelons) of defense. Thus, NPP I&C architectures provide progressively compensating systems for “active” control and protection, even should one or more of the systems fail.

DiD within I&C architectures provides independent means to maintain desired operational conditions, prevent accidents, and ensure adequate protection during adverse events (e.g., failures). The U.S. NRC has identified four echelons of defense. These overlapping and redundant systems are defined as the RTS, the ESFAS, the plant control system, and the monitoring and indicator system(s) in the main control room. The means of accomplishing a safety objective for a specific echelon of defense can involve either avoidance of adverse conditions or mitigation of their effects.

A companion safety principle in the application of DiD within an I&C architecture is independence, which has the objective of preventing the failure of one system from inducing the failure of another system. This objective is achieved by the enforcement of independence among the echelons of defense. Independence is ensured through physical separation, electrical isolation, and functional segregation. The I&C systems must not be coupled physically, electrically, or functionally to ensure that failure of one system does not compromise the function of other systems. The capability of digital technology to aggregate functions and interconnect systems through networking poses a special challenge to ensuring independence among digital systems. Thus, I&C systems designs consider communications independence so that an echelon does not functionally depend on output (e.g., data, commands) from other echelons.

Another safety principle arises from the single failure criterion expressed in the GDC. A single failure is a random occurrence that results in the loss of capability of a system to perform its safety functions. The common approach to address single failures is the application of redundancy as a design principle for safety systems. Consequently, protection systems, such as RTS and ESFAS, consist of independent redundant divisions supporting a voting scheme for actuation, as described in the discussion of safety system architectures above. The independence of the divisions (or channels) is maintained from the sensor through the system voting. In effect, each division consists of dedicated sensors and electronics that are redundant to and independent of the equipment of the other divisions. Thus, the failure of one division does not propagate to affect the function of the other divisions. Additionally, the voting of the division commands for actuation mitigates the failure of any one division. Digital technology offers the capability for self-testing and error-checking and the avoidance of single random failures because such conditions can be more readily detected and mitigated than for analog systems.

The safety principle of diversity and DiD, or D3, serves to address the potential for concurrent failure of multiple systems or divisions due to activation of a systematic fault common to each system. This vulnerability is of special concern for safety systems because they operate in an on-demand fashion (i.e., safety systems only take action when a PIE is detected). Consequently, safety systems subject to CCF can “fail silent,” resulting in their undetected unavailability should a design basis event occur. Common systematic faults can result from various sources (e.g., requirements deficiency, implementation error, or manufacturing defect) and may not be detected during design, implementation, or acceptance testing. By itself, the redundancy of identical divisions in safety systems offers no protection against CCF. Thus, even for well-established analog-based I&C system designs, the potential for CCF of multiple systems (or redundancies within a system) constitutes the principal credible threat to defeating the DiD provisions within NPP I&C system architectures. For analog safety systems, the primary approach to address CCF is to establish suitability through equipment qualification and thereby minimize the potential for a common environmental stressor to cause concurrent failure of redundant equipment. It is generally accepted that the unique characteristics and inherent complexity of digital I&C systems can exacerbate vulnerability to CCF.

Diversity, in the context of DiD, is the primary means employed to address CCF vulnerability. The principle of D3 was employed in the first reactor, Chicago Pile #1 (CP-1). For CP-1, three reactor trip capabilities were provided: (1) automatic control rods, (2) a manually initiated, gravity-driven shutdown rod, and (3) manual liquid control (i.e., reactivity control by flooding the pile with a cadmium-salt solution). Thus, the original application of DiD for safety systems was enhanced by equipment and functional diversity, which relate to different actuation means and different underlying methods, respectively.

The approach to ensuring safety through diversity provides different means to accomplish the same or equivalent function to compensate for a CCF that disables one or more echelons of defense. Thus, diversity is complementary to the principle of DiD and increases the likelihood that a line of defense will be actuated when needed. For current NPPs that have primarily analog-based safety systems, diverse anticipated transient without scram (ATWS) systems are employed to provide additional safety assurance through alternate means of responding to design basis events. For more recent NPPs and those undergoing extensive modernization, the common approach is to implement a non-safety diverse actuation system (DAS) to act should the safety systems fail due to CCF.

The application of diversity to I&C systems involves approaches such as sensing different parameters, using different technologies, using different logic or algorithms, or using different actuation means to provide several ways of detecting and responding to a significant event. As noted in the CP-1 example, the foundational use of diversity involved functional diversity. In common practice, functional diversity is generally coupled with signal diversity. Basically, different underlying methods to detect design basis events is achieved by using different sensors (e.g., pressure vs. temperature) to serve as diverse indications of PIEs.

For digital I&C systems, the potential for and consequences of CCF are evaluated through a D3 analysis (U.S. Nuclear Regulatory Commission, 1994). Based on analysis results, diversity may be introduced into the I&C system architecture to mitigate identified CCF vulnerabilities. The value of diversity for digital I&C architectures arises because dissimilarities in technology, function, implementation, and so forth can mitigate the potential for undetected common faults among redundant divisions or independent echelons of defense. Diversity for digital I&C systems is characterized in terms of design, functional, signal, equipment, software, and human (system lifecycle) attributes.

Quality assurance

The regulations in 10 CFR 50 specify that consensus standards and quality assurance practices must be applied in the design, development, implementation, testing, installation, and operation of safety systems. Specific criteria for quality assurance are provided in Appendix B of 10 CFR 50. These criteria are supplemented by regulatory guidance on software quality assurance practices that apply to the entire system lifecycle, from requirement specification to retirement. In the design and development of software, extreme care is assured by requiring a detailed formal program with well-developed and independently verified plans. These plans and associated procedures address aspects of the digital system lifecycle such as requirements and design specifications, design, development, configuration management, installation, testing, maintenance, software management, verification and validation program, operations, lifecycle maintenance. These programs and plans are based on consensus standards and provide the means for developing high integrity software for reliable operation of a safety system.

The nuclear industry typically obtains its components from vendors who adhere to nuclear-grade quality assurance practices. However, because of the small market for nuclear I&C equipment, the availability of nuclear qualified equipment suppliers is limited. Consequently, it is becoming more common for the nuclear industry to employ commercial off-the-shelf (COTS) digital equipment. While this approach brings with it the advantage of the lower cost, a large user base, and an extensive history of performance, it is necessary for the NPP to demonstrate that the equipment meets the same or equivalent quality requirements as nuclear-grade equipment. As a result, it has become a common practice for utilities and other companies to purchase COTS or commercial-grade items and then to qualify them for use in safety systems by performing a special dedication process.

Cyber security

This issue requires the development and implementation of a security program to protect critical digital assets from cyber attack. There are both software and hardware aspects to cyber security. The hardware can be protected by isolating the safety system from external networks and establishing an internal network which allows only one-way communication from the safety system to any other I&C or data systems in the plant. The software, however, can be more problematic because of the need to provide security throughout the supply chain. If the software-based system or its digital support services are altered or infected, either during development or later, then the vulnerabilities to malicious attack or intrusion can be introduced that may result in anomalies in reactor operation or compromise of control system and/or safety system functions. The U.S. NRC has several recommendations for establishing cyber security for digital assets to preserve and protect software integrity.

Integral and small modular reactors

Several designs of small modular reactors (SMRs) are being developed by reactor vendors. The SMRs range in capacity from 25 to 300 MWe. The capability to implement nuclear power plants based on smaller reactors can help match the energy needs for regions of the world that lack highly stable, densely interconnected electrical grids. These reactors can present lower capital costs than large reactors, allow for incremental additions to power generation capacity, and support multiple energy applications (i.e., power generation and process heat supply). The design and configuration of these reactors provide enhanced safeguard capability. Additionally, SMRs can be introduced through phased construction of modules at a plant site to incrementally achieve a large-scale power park (Ingersoll, 2021).

The SMR designs under development include innovative light-water-cooled reactor concepts as well as non-water-cooled reactor concepts. The light-water-cooled reactor concepts tend to be integral primary system designs, in which all of the major NSSS components are in a large reactor vessel. These include reactor core, control rod drive mechanisms, steam generators, coolant pumps, and

in some cases residual heat removal system. SMRs are designed for possible remote deployment with remote monitoring and operation. Ingersoll (2021), and Carelli and Ingersoll (2014) provide excellent descriptions of both light water and other types of SMRs.

As an example of a near-term SMR concept, the U.S.-developed SMR design by NuScale Power is an integral PWR rated at 50 MWe per unit, with natural circulation of the primary coolant. The reactor vessel contains all the NSSS components and is housed in a steel containment which is submerged in a large pool of water. The power generation station is designed for 12 units with a single control room.

Realizing the benefits of SMR deployment requires innovation and advanced capabilities development of I&C technologies to address management of multi-unit, multi-product-stream generating stations and to offset the reduced economy-of-scale savings. Additionally, the unique characteristics of SMR designs compared to traditional reactor designs pose some technical challenges that remain to be resolved. As an example, the unusual geometry and internal flow paths for integral reactors presents a challenge in the measurement of process parameters, as well as neutron flux, that emphasizes the value of in-vessel sensors. IAEA Nuclear Energy Series (2017) describes the characteristics of SMRs that affect the design and implementation of I&C systems and discusses the distinctive features and issues of I&C technologies relevant to SMR plant management and operation.

Summary

Instrumentation and control systems serve as the ‘central nervous system’ of a nuclear power plant. This chapter provides brief descriptions of process instrumentation and neutron detectors used in light water reactors. Reactor control strategies implemented in PWRs and BWRs are presented. The chapter provides a summary of digital I&C. Some of the operating reactors are being modernized with digital systems. New designs of light water reactors utilize digital I&C.

The licensing aspects of digital I&C, including probabilistic risk assessment, are not presented in this chapter. They are covered in Section 4 of this encyclopedia.

Glossary

AFD Axial flux difference is the difference between the core power generated in the upper half of the core and the lower half, normalized to the total core power. The operational goal is to maintain AFD within a relatively narrow band around zero.

Burnup A measure of the amount of fission energy released from a given mass of uranium (heavy metal). Unit is Megawatt-days per kilogram (MWd/kg), or Gigawatt-days per ton (GWd/ton). Also referred to as exposure.

BWR Boiling water reactor. See [Hamon \(2021\)](#) for detailed description.

CRD Control rod drive system is the mechanism used to control insertion or extraction of the control rods.

CVCS Chemical and volume control system in a PWR. See section “PWR operation” for detailed description.

Drywell A steel or concrete structure surrounding the reactor vessel in a BWR. It is designed to contain steam released in a loss of coolant accident, and channel it to a water pool for condensation.

IAEA The International Atomic Energy Agency (IAEA) is an international organization that seeks to promote the peaceful use of nuclear energy, and to inhibit its use for any military purpose, including nuclear weapons. The IAEA was established as an autonomous organization on 29 July 1957.

K_{eff} The ratio of rate of production of fission neutrons to the rate of neutron losses (via absorption or leakage). In critical reactor K_{eff} value is maintained at 1.0.

Mode The state of the reactor during startup, normal operation, and shutdown.

Moderator Substance used to slow neutrons generated by fission and with features an efficient neutron kinetic energy loss per collision.

MTC Moderator temperature coefficient (MTC): The effect of a change in the moderator temperature on the core reactivity ($\Delta K_{eff}/K_{eff}/^{\circ}\text{C}$).

^aRetired.

NA Not applicable. Refers to certain table entries in this article that do not contain any information.

Neutron flux Number of neutrons crossing a unit area per second. Reaction rates, such as the fission rate, are proportional to the neutron flux.

NOP/NOT A term used in reactor startup operations to indicate: Normal operating pressure/normal operating temperature

PCI Pellet-cladding interaction. See [Young \(2021\)](#) for details.

PWR Pressurized water reactor. See [Brown \(2021\)](#) for details.

RCA Reactivity control assembly. See [Young \(2021\)](#) for details.

RCS Reactor coolant system. See section “PWR operation.”

Reactivity A term expressing the departure of a reactor system from criticality. A positive reactivity addition indicates a move toward supercriticality (power increase). A negative reactivity addition indicates a move toward subcriticality (power decrease).

RFP Reactor feedwater pump. A pump or pumps designed to provide feedwater to the reactor vessel (BWR).

RHR Residual heat removal system. See sections “PWR operation” and “BWR operation.”

RWCU Reactor water cleanup system. See section “BWR operation.”

SJAE Steam jet air ejectors are devices used to remove non-condensable gases from a steam system.

Technical Specifications A set of conditions or limits that must be met before a reactor can remain at power or change a reactor condition. Establishes requirements for items such as safety limits, limiting safety system settings, limiting control settings, limiting conditions for operation, surveillance requirements, design features, and administrative controls.

USNRC The United States Nuclear Regulatory Commission is the principal government body charged with establishing regulations to ensure the safety of nuclear power plants in the United States.

Xenon A decay product (Xenon-135) created during the fission process. It has a large neutron cross section, which acts to suppress local reactor power. Significant changes in local reactor power affect xenon concentrations, which in turn affect local core reactivity.

Introduction

Reactor operations comprise the activities involved in maintaining the reactor in a stable configuration while operating, and, at intervals of 1 to 2 years, bringing the reactor to zero power and atmospheric pressure so that fuel can be replaced and maintenance performed. These activities are described in this article.

The startup, normal operation and shutdown operations are described separately for the PWR and BWR. The PWR is assumed to be a four loop Westinghouse design, and the BWR is assumed to be a General Electric BWR/4. Other designs will differ in some details, and these differences will be discussed as appropriate. Some of the materials for this article were derived from materials available in the USNRC public document room ([USNRC, 2002a](#)) and ([USNRC, 2002b](#)).

PWR operation

Several components of the plant play critical roles in reactor startup and normal operation and are listed here in summary form. Details on these components are provided in ([Brown, 2021](#)).

Reactor coolant system (RCS): this system consists of the reactor vessel containing the core, pipes connecting the reactor vessel to the steam generators, and reactor coolant pumps to circulate the pressurized water.

Residual heat removal system (RHR): this system’s main function is to provide water to the core during a loss of coolant accident. In normal operation it is secured, but ready for use in case of emergency. During refueling operations, it also serves to remove residual heat and maintain sufficient flow through the core.

Chemical and volume control system (CVCS): this system controls the chemistry of the coolant during normal operation, in particular the concentration of the boron in the water moderator. It also serves to remove corrosion products from the coolant. During refueling and startup it is used in conjunction with the RHR to control pressure and temperature.

Control rods: Control rod movement is important to control both power level and power distributions during normal operation, and to shut down the reactor, as needed. Control rods in a PWR are grouped into “control banks” and “shutdown banks.” These banks are “stepped” into or out of the core by latching mechanisms in the control rod drives, attached to the reactor vessel head. Shutdown banks are used to help shut down the reactor. At a reactor trip signal, all banks are released into the core.

Nuclear instrumentation: The type of instrumentation used to measure neutron flux varies by reactor design. In current Westinghouse reactors, nuclear instrumentation located just outside the reactor vessel (ex-core) monitors the power level by detecting neutron leakage from the reactor core. The neutron flux (neutrons/cm²/s) generated in the core, from shutdown conditions to 100% power, ranges from a few neutrons/cm²/s to over 10¹⁵ neutrons/cm²/s. This large range requires three types of detectors with overlapping ranges. The three different types of neutron detectors are designated source, intermediate, and power. Each

detector is specifically designed to accurately measure neutron flux in its designated range. The source range detector operates when the reactor is critical but is producing essentially zero power. It is typically a proportional counter (Han, 2021) that detects ionization events (counts per minute) directly. The intermediate range detector, active up to 120% of rated power, is typically a compensated ionization chamber, where the neutron flux induces a current in the detector circuitry (hence, the power state of the reactor in this range is described in terms of “amps,” where 10^{-8} amps corresponds to approximately 0.001% thermal power). The power range detectors, applicable from 1% to 120% power, are also ionization chambers, calibrated to convert the neutron flux measured to percent rated thermal power.

Reactor startup

Reactor startup proceeds in the form of a countdown, through a series of “Modes.” These are specifically defined in the plant Technical Specifications (USNRC, 2012a, 2012b) as shown in Table 1 below. The values given below for average coolant temperature are from the Standard Technical Specifications; there may be some variation among plants. These specifications tightly control the tests that shall be performed and the conditions that must be met prior to proceeding to the next Mode.

Heatup and power ascension (Modes 4 to 2)

The startup evolution begins from the point when the core has been refueled, the reactor vessel has been resealed, and the RCS has been filled with water. The reactor coolant pumps are off, so coolant circulation is maintained by the RHR pumps. The reactor core is generating a small amount of residual heat at this time. This heat is removed from the core by the RHR system.

The RCS is completely full of water, and the pressure in the RCS is controlled between 320 and 400 psig (2–3 MPa) by maintaining a flow balance between the coolant removed from the RCS, referred to as letdown flow, and the coolant being returned, referred to as charging flow, using both the RHR and the CVCS. The steam generators are in “wet layup,” filled to the 100% level with water, and all secondary systems are secured with the exception of one circulating water pump. The main turbine and both feedwater pump turbines are on their respective turning gears (slowly being rotated to prevent distortion of the heavy turbine rotors). All pre-startup checklists have been completed.

Heatup

A steam bubble is first established in the pressurizer. This ensures that a compressible volume is available in the pressurizer for water expansion caused by the heatup of the coolant. Steam bubble formation in the pressurizer is accomplished by heating the water volume of the pressurizer with the pressurizer heaters. With a steam bubble established in the pressurizer, RCS pressure is controlled by pressurizer heater (to generate steam in the pressurizer) and spray valve operation (to condense steam).

Once a steam bubble is established in the pressurizer, the reactor coolant pumps are started. After all reactor coolant pumps are operating, the RHR pumps are stopped, since they are no longer needed to remove decay heat or to provide forced flow through the core. With all RCPs operating and the RHR system secured, the reactor coolant begins to heat up at a rate of approximately 50 °F (10 °C) per hour, due to the heating energy supplied by the RCPs.

Steam formation begins in the steam generator secondary side. The reactor is now in Mode 4 (Hot Shutdown).

The RCS continues to heat up, until it reaches normal operating pressure and temperature (referred to as NOP/NOT), typically 2250 psia (15.5 MPa), 570 °F (300 °C). The RHR system is now isolated from the RCS and aligned for its normal emergency cooling function. The reactor is still subcritical.

The primary plant heatup is limited by automatic actuation of the steam dumps when the pressure inside the steam header reaches its normal operating pressure, approximately 1000 psig (6.9 MPa). The RCS temperature remains constant, with the steam dumps removing any excess energy that would tend to drive the RCS temperature higher. The reactor is now in Mode 3 (Hot Standby).

Reactor coolant leak rate tests and control rod drop tests are normally conducted at this point.

Power ascension

Boron concentration in the coolant is first adjusted so that the reactor will be near critical at a given desired control rod position. Control rods are then withdrawn in steps to establish criticality. Criticality is reached when there is a steadily increasing source range

Table 1 Typical PWR modes for startup.

Mode	Title	Core reactivity condition (K_{eff})	% rated thermal power	Average reactor coolant temperature
1	Power Operation	≥ 0.99	> 5	NA
2	Startup	≥ 0.99	≤ 5	NA
3	Hot Standby	< 0.99	NA	≥ 350 °F (177 °C)
4	Hot Shutdown	< 0.99	NA	200 °F (90 °C) to 350 °F (177 °C)
5	Cold Shutdown	< 0.99	NA	≤ 200 °F (90 °C)

count rate with no control rod withdrawal. After criticality is achieved, the control rods are positioned to increase nuclear power until the intermediate range instruments read 10^{-8} amps (equivalent to approximately 0.001% thermal power). Power is stabilized at this level to record actual critical conditions. Various physics tests are performed to confirm the nuclear characteristics of the core. These data include:

Critical boron concentration (all rods out)
 Moderator temperature coefficient (MTC)
 Control rod reactivity worth
 Core power symmetry

After recording the critical data, the control rods are positioned to increase power to the point of adding heat, approximately 1% power as indicated on the power range instruments, and then to stabilize power at about 2%. As nuclear power increases above the point of adding heat, the fuel and moderator temperatures increase. These temperature increases add negative reactivity because of the negative fuel and moderator temperature coefficients.

As the moderator temperature increases, the coolant expands into the pressurizer, causing the level and pressure to increase. Also, the steam generator temperatures and pressures begin to increase. The steam dump valves modulate open, maintaining the steam generator header pressure at approximately 1000 psia (6.9 MPa).

The power level is maintained at 2% while a main feedwater pump is started and aligned to supply the steam generators through the main feed regulating bypass valves. With a main feedwater pump feeding the steam generators and the auxiliary feedwater system realigned to its normal at-power standby lineup, turbine startup may proceed. When the reactor power reaches and exceeds 5% of rated power, the plant is in Mode 1 (Power Operations). The Technical Specifications for power operation then apply.

With nuclear power at 15%, the main turbine is rolled off the turning gear and accelerated to a specified rpm. With the turbine running, the turbine auxiliary systems are aligned for normal operation, and the turbine protection system is tested to verify proper operation. Generator synchronization is performed after satisfactory turbine protection system testing.

When the main generator voltage, frequency, and phases are matched with those of the grid, the generator output breakers are closed, and the generator picks up a minimum load (typically, approximately 60 MWe for a large nuclear unit). The operators can now increase the generator's electrical output to the grid. To prevent axial xenon oscillations and to maintain peaking factors within Technical Specification limits, the operator must insure that the indicated axial flux difference (AFD) is maintained within predefined limits during power ascension and when full power is achieved (see section "Normal Operation" for description of AFD measurement). This is accomplished by applying strict limits to the rate of removal of control rods. At approximately 50% load, a calorimetric calculation (heat balance) is performed on the secondary system, and an adjustment to the power range nuclear instruments is performed, if necessary. Further calorimetric calculations are performed at 90% and 100% power. These additional calculations are performed to ensure that the power range nuclear instruments are properly calibrated.

Full power operations

During normal operation, all control rods are typically fully withdrawn, and reactivity is controlled by boron in the coolant. The boron concentration typically increases early in the cycle to offset increasing core reactivity as burnable poisons (Young, 2021) within the fuel are burned out, then decreases as fuel is depleted.

Core power is generally controlled by control rod insertion. At all times when the reactor is critical, the control banks must be maintained above their respective insertion limits. Maintaining the rod banks above their respective insertion limits ensures that sufficient negative reactivity is available to achieve and maintain the required shutdown margin in the event of a reactor trip.

For a PWR, the response of the RCS (the primary side) to a change in turbine load occurs at the heat transfer interface with the steam generators (the secondary side). At the simplest level, the heat transfer from the primary side to the secondary side is proportional to the difference between the average reactor coolant temperature, T_{avg} (essentially the average of the core inlet and the core exit temperature), and the average steam-water mixture temperature on the secondary side, T_{stm} . Since the secondary side is a steam-water mixture, the secondary side temperature varies directly with pressure. For example, as turbine load increases, secondary side temperature and pressure fall as more energy is removed than supplied. Increased heat transfer from the primary then reduces T_{avg} . For a PWR, in response to this change, three options are possible:

1. Maintain primary side T_{avg} constant, and let the reduced secondary side temperature increase the heat transfer from the primary side as needed. This requires a minimal change in reactivity, but has the disadvantage (among several others) of significantly reducing steam pressure, with a corresponding deteriorating steam condition (increased moisture carryover).
2. Increase reactor power to increase T_{avg} , so that the secondary pressure remains at the optimal value. The disadvantage here is the potential for significantly higher core exit temperature, which has an adverse effect on system materials, and may cause some bulk boiling in the higher powered assemblies.
3. The optimal approach, taken by all PWRs today to varying degrees, is a combination of options 1 and 2: allow T_{avg} to increase slightly (along a programmed trajectory), with an increase in turbine load. Steam pressure and temperature will fall slightly, but within acceptable limits.

Operating strategies

Baseload operation

This has been the traditional operational strategy for PWRs (and BWRs, see below). The reactor operates at 100% power, 24 h a day, 365 days a year, for up to 2 years, until the fission chain reaction can no longer be sustained and the reactor must be refueled. Normally in a PWR, all control rods are out, and core power is maintained by slowly reducing the amount of boron in the coolant or other poisons in the core. Short term responses to turbine load are accomplished by control rods.

Recently, a “coast down” period has been added to the last few months of the cycle, to increase fuel utilization. In this operational mode, boron has been diluted to the maximum extent practically possible. Core power slowly declines to approximately 80–90% until the plant is shut down for refueling.

Load follow operation

PWR's (and BWR's, see below) have been designed to allow the reactor power to be reduced and increased in a programmed fashion depending on the electricity demand from the grid. In a PWR, reactor power is reduced by adding boron to the coolant, and partially inserting selected control rods. The power change must be accomplished such that changes in axial offset (difference between power in the top half and bottom half of the core) are maintained within limits established in the Technical Specifications. In the United States until recently, it has been more economical to manage load demand by temporarily shutting down or throttling down other generation forms (which comprise over 80% of the total generation). In contrast, in France, where a much larger fraction of the total electrical power is generated by nuclear, other options for responding to load demand do not exist. Consequently, the PWRs in France have operated in load follow for years.

In a load follow operation, the core power is reduced from 100% over several hours to a predetermined level, typically not less than 70%, and then maintained at that level for several days. The power reduction is primarily achieved by control rods, assisted by boron concentration increase. As originally envisioned, load follow would occur at regular, preplanned intervals.

Flexible operation

Flexible operation is essentially load follow, except that required response times are generally much shorter, and the times during which the reactor is at lower power can vary from a few hours to weeks. This is the result of intermittent forms of electricity production, such as wind turbines or residential solar panels that have been connected to the grid. Changes in electricity production from these alternative forms cannot be easily planned in advance.

Economics of load follow operation in PWRs

Reactor operating costs generally fall into three categories:

1. Capital costs
Most power reactors such as those described here have been designed to allow safe operation while responding to changing grid demands, so additional capital investment to allow a plant to load follow is generally small.
2. Operation and maintenance costs
Operation and maintenance (O&M) costs cover all the costs of operating the plant, maintenance and repair, and replacement of supplies and equipment.
3. Fuel cycle costs
Fuel cycle costs generally encompass the cost of uranium mining, enrichment, and the manufacturing of fuel assemblies.

The preferred operational mode for nuclear reactors is, for fairly obvious reasons, base load operation. This is reinforced by economic analysis (Rothwell, 2021) demonstrating that minimizing operating costs and fuel costs while maximizing annual power output are key to reducing the cost of nuclear electricity production for a specific reactor. Minimizing changes in reactor conditions also minimizes operation complexity, wear and tear, and fuel costs. As explained, however, in a recent IAEA publication (IAEA, 2018), consideration of the overall makeup of the electric grid and its various generating sources often takes precedence over increased reactor operating and fuel costs.

Surveillance

Normal operation

During normal operation, the ex-core and in-core instruments described at the beginning of section “PWR operation” are used to monitor for any changes in the overall core power distribution. In particular, the axial flux difference (AFD), the difference in power between the top and bottom of the core is determined from the ex-core power range measurements. This measurement must be kept within specific limits established by the core design and safety analysis at all times.

In addition, detailed assembly power distributions are determined. This is accomplished through use of in-core instrumentation. In most Westinghouse PWRs, the instrumentation, consisting of miniature fission chambers (Han, 2021) and contained within a long sheath, is inserted through the bottom of the reactor vessel into the central guide tube of selected assemblies. The instrument is moved axially within the assembly to measure the local neutron flux. In other PWRs, the instruments remain in place in the core, and measure the local power distribution continuously (while the in-core instrumentation provides real-time data, it is less

detailed). Data from these more detailed measurements are used to confirm maximum local fuel rod linear powers (expressed as kW per meter or per foot of fuel rod, and discussed further in Young, 2021) are also within Technical Specification limits.

At startup and during normal operation, calorimetric calculations (essentially a heat balance, establishing the steam flow and change in enthalpy between the supplied feedwater and the generated steam) are performed to confirm agreement with core power calculated from the nuclear instruments.

In addition, coolant samples are taken at regular intervals, and tested for the presence of various elements and radioisotopes. Generally these measured quantities fall into three categories and indications:

- (a) Boron, lithium, hydrogen: Boron is crucial in controlling core reactivity. Lithium controls the reactor coolant pH, which in modern PWRs is usually set at a constant target value of 7.0–7.2. Hydrogen is added to the coolant via the pressurizer vapor space to ensure that any excess oxygen, which affects corrosion rates, is quickly removed.
- (b) Coolant radio isotopes that are created from stable nickel (Co-58), iron (Mn-54), and chromium (Co-60) isotopes that comprise the major structural materials in a PWR are monitored to confirm no departure from historical values. Departures may indicate unusual corrosion rates or other changes.
- (c) Fission products such as iodine (I-131) and xenon (Xe-133) are monitored. Large changes indicate the presence of leaking fuel rods.

Additional reactor monitoring during normal operation include:

- (d) Control rod drive testing: control rods are moved down and up a few steps, sufficient to confirm the control rod drive mechanisms are operational, without affecting the core power distribution significantly.
- (e) Calorimetric tests to confirm reactor power

The description above does not include the many surveillance functions performed automatically by the reactor protection system. This system continuously monitors system pressure, flow, and many other operating parameters to determine if a serious malfunction has occurred and to automatically activate the safety systems to shut down the reactor.

Reactor trips and restarts

Reactor trips and reductions in power tend to be rare in today's reactors, occurring about once every few fuel cycles. For a shutdown, the reactor is usually maintained in Mode 2 while the problem is addressed. Normally restart occurs within a few hours or days. A typical restart proceeds by removing control rods to achieve 50% power, maintaining this power for a specified hold period, then continuing the power ascension in steps to 100%, again with specified hold periods in between. These hold periods are put in place to allow the fuel rods to "re-condition" to the increased power. The conditioning process that PWR fuel rods require following a power change is similar to that for a BWR and is described in additional detail in the section BWR: Flexible Operation.

Normally, returns to 100% power from reduced power conditions such as occur during load follow can be implemented without any required hold periods, provided the change is of relatively short duration.

Reactor shutdown for refueling

The procedure for reactor shutdown is essentially the reverse of the startup procedure with some key differences. A key objective is to minimize the potential for uncontrolled release of activated corrosion products, initially residing on the core, to the rest of the RCS. To accomplish this, the RCS is first exposed to an acid reducing environment by removing lithium from the coolant, reducing the pH. The purpose is to reduce any accumulated nickel oxide to nickel, so it will be susceptible to dissolution when the chemistry becomes oxidizing. In addition, there will be some limited dissolution of other corrosion products such as nickel ferrite and activated corrosion products. The coolant is then converted to an oxidizing environment. This dissolves most of the Ni and Co-58 metals, and smaller amounts of Fe, Mn-54, and Co-60, which can then be removed by ion exchange before the RCS is opened to the atmosphere. The large amounts of nickel and Co-58, relative to other metals, are due to the large surface area of nickel alloy steam generator tubes that exist in a US PWR. Co-58 generally poses the greatest challenge to maintaining low dose rates during refueling.

A typical shutdown proceeds as described below, although there may be significant differences in the timing and use of RCPs among plants.

Prior to shutdown, one of the mixed bed demineralizers will have the resin replaced with a dual purpose charge that will also remove lithium and will have sufficient capacity to clean up the RCS (including potential elevated Co-58 or Co-60) throughout the shutdown period.

The outage starts when main generator load and reactor power are reduced to 15%. Main turbine overspeed trip testing is typically performed next. Immediately following completion of the overspeed test, reactor power is reduced to less than 5%, and with the reactor in Mode 2 the control rods are inserted to enter Mode 3. Emergency boration is initiated as soon as Mode 3 is entered, and with continued lithium removal, acid reducing (low pH) conditions are achieved in the coolant.

A few hours after reactor shutdown, cooldown from normal operating temperature is initiated, to reach Mode 4 (177°C) within a few hours. During the time period that acid reducing conditions exist, letdown purification flow is maintained as high as possible to remove the corrosion products that are being dissolved. Adjusting RCS inventory is accomplished, as in startup, by adjusting charging flow while keeping letdown flow constant and maximized.

All except one of the reactor coolant pumps are typically secured after reactor shutdown and prior to Mode 5 to minimize heat input and pressure drop loading of the reactor internals.

With RCS pressure less than 1000 psi (6.8 MPa), accumulators (large tanks with water that are used in the event of a loss of coolant accident) are isolated and the RCS pressure is reduced to less than 360 psi (2.5 MPa). Then RHR shutdown cooling is established. Cooldown from approximately 175°C to 90°C on RHR generally requires a few hours. When the RCS temperature falls below 90°C the RCS is taken water solid (pressurizer full).

After approximately 12 h of acid reducing conditions, the dissolved Co-58 activity level is expected to have increased by a factor of about 10. Increases in iron, Mn-54, and Co-60 also occur, although these levels are much smaller.

The next phase in the shutdown procedure is to achieve acid oxidizing conditions, by adding hydrogen peroxide into the RCS. The dissolved Co-58 activity level is expected to increase by another factor of 10 during this time.

During the peroxide addition activities, the RCS is cooled down to between 60°C and 35°C with one RCP operating. The RCS is further depressurized and then partially drained for reactor disassembly.

When the cleanup endpoint is reached, the flood up of the reactor cavity is initiated. With the cavity flooded it is desirable to maintain RHR letdown purification in operation, to the maximum extent possible, to continue to remove corrosion products that are being dissolved at a reduced rate.

Reactor disassembly and refueling operations

The disassembly of the reactor vessel begins with the removal of the missile shield. All cables, air ducts, and insulation are then removed from the vessel head. The thermocouple leads are disconnected from the reactor vessel head, and protective covers are installed over the top of the thermocouple support columns. The in-core instrumentation thimbles are disconnected and pulled back through the bottom of the vessel. The reactor vessel stud tensioners are used to de-tension the vessel studs, and after removal of the studs, stud hole plugs are installed to protect the threads (three stud holes are left unplugged and are fitted with threaded guide studs which help to position the various lifting rigs).

The refueling cavity is prepared for flooding by sealing off the reactor cavity and removing the blind flange from the fuel transfer tube. With the refueling cavity prepared for flooding, the vessel head is unseated and raised approximately 1 ft above the vessel flange. The vessel head and the water level in the refueling cavity are raised simultaneously, keeping the water level just below the head, so that the head can provide temporary protection from radiation. When the water reaches a safe shielding depth, the vessel head is taken to its storage pedestal. The control rod drive shafts are then disconnected and, with the upper internals, are removed from the vessel and placed in their temporary storage location. The fuel assemblies and rod cluster control assemblies are now free from obstructions and the core is ready for refueling.

Fuel handling can start after the reactor has been subcritical for 100 h (Technical Specification requirement). This allows time for the short-lived fission products to decay. The refueling sequence is started with the manipulator crane. As determined in the refueling guide, which is prepared before each refueling, used fuel assemblies are removed from the core. The positions of partially used assemblies that will be operated for a second cycle are changed and new assemblies are added to the core. This process is called a fuel shuffle. The fuel assembly loading and reloading procedure proceeds in a pattern that minimizes the risk of interaction between assemblies. In some cases, the entire core is offloaded, then replaced (with fresh and partially used assemblies).

The fuel handling sequence proceeds as follows:

The manipulator crane is positioned over a fuel assembly in the core. The fuel assembly is lifted by the manipulator crane to a predetermined height sufficient to clear the reactor vessel and still leave sufficient water covering to eliminate any radiation hazard to the operating personnel.

If the removed fuel assembly contains a rod cluster control assembly (RCCA), the fuel assembly is placed in a special fixture where the rod cluster control assembly is removed from the spent fuel assembly and placed into a new or partially used fuel assembly also located in the change fixture.

The fuel transfer (conveyor) car is moved into position in the transfer canal in the containment near the upender, which is used to switch the fuel assembly between horizontal and vertical orientations. The fuel assembly container section of the transfer car is pivoted to the vertical position by the upender, and the manipulator crane is moved to line up the fuel assembly with the fuel transfer system. The manipulator crane loads a fuel assembly into the container section of the conveyor car. The container is then pivoted to the horizontal position by the upender, and the fuel assembly is moved through the fuel transfer tube to the spent fuel pool. There, the fuel assembly container is raised to the vertical position by the upender, the fuel assembly is unloaded by the spent fuel pool bridge crane, and a new fuel assembly is brought from dry storage, and loaded into the fuel assembly container of the transfer car. The fuel assembly container is pivoted to the horizontal position and the conveyor car is moved back into the containment, where the assembly is relocated in the core.

Plant activities during a refueling outage

A refueling outage represents a critical time period for the operating success of a nuclear reactor. In addition to replacing the fuel, it is the only time when large portions of the reactor and its supporting systems, including the secondary side, are accessible for equipment inspection, maintenance, and replacement. Examples of typical activities are:

Pump and valve inspections and repair.

Metallurgical inspections of various components of the pressure boundary such as the reactor vessel and the steam generator tubes.

Containment inspections.

On the other hand, every day not producing power is a significant cost impact. Consequently, the refueling outage is generally scheduled for times when electricity demand is lower (in the United States, this is in spring or fall). The outage is packed with hundreds of activities performed around the clock, all planned months in advance with tightly controlled schedules. The workforce during a refueling outage typically increases from a few hundred to potentially several thousand workers. The resident inspector from the US Nuclear Regulatory Commission is also at the reactor site observing the activities. Typical well-planned and executed refueling outages are accomplished within 1 to 2 months.

Reactor re-assembly and startup

Reactor assembly, following the refueling outage, is essentially achieved by reversing the operations described in the beginning of this section. Startup then proceeds as described at the beginning of this section.

BWR operation

Several components of the plant play a role in reactor startup and normal operation and are listed here in summary form. Details on these components are provided in [Hamon, 2021](#).

Reactor coolant system (RCS): this system consists of the reactor vessel containing the core and steam separators, pipes connecting the reactor vessel to the steam turbines, and the recirculation loop and associated pumps.

Condensate and feedwater system: The condensate and feedwater system collects condensed steam, purifies, preheats, and pumps water from the main condenser to the reactor vessel.

Residual heat removal system (RHR): This system's main function is to provide water to the core during a loss of coolant accident. In normal operation it is secured, but ready for use in case of emergency. During refueling operations, it also serves to remove residual heat and maintain sufficient flow through the core.

Reactor water cleanup system (RWCU): The reactor water cleanup system maintains reactor water quality by filtration and ion exchange and provides a path for removal of reactor coolant when required.

Control rod drive system (CRD): positions control rods within the reactor core to change reactor power or to rapidly shutdown the reactor. These positions are referred to as notches, since there are mechanical stops that lock the CRDs into position. Typically, a notch is a discrete movement of 6 in. (15.2 cm) for the Generation II BWRs. The control rod is held at a given position by a collet engaging one of several notches in an index tube. The control rod is moved by applying pressure (via an accumulator) greater than reactor pressure to either the top or bottom of a main drive piston. Control rods are designated in groups. Only a selected number of groups are chosen to control reactor power during normal operation. These groups are banked into or out of the core as needed. The remaining groups of control rods are used to help shut down the reactor. At a reactor trip signal, all groups are driven into the core. Loss of electrical power to the system or reduction of accumulator pressure results in opening of scram pilot valves, thereby causing the rapid shutdown of the reactor.

Nuclear instrumentation: BWRs have various in-core nuclear instrumentation to measure neutron flux. The neutron flux (neutrons/cm²/s) generated in the core, from shutdown conditions to 100% power, ranges from a few neutrons/cm²/s to over 10¹⁵ neutrons/cm²/s. This large range generally requires three types of detectors with overlapping ranges. The three different types of ranges are designated source, intermediate, and power. Each detector is specifically designed to accurately measure neutron flux in its designated range. The source range detectors operate when the reactor is critical but is producing essentially zero power. It is typically a proportional counter that detects ionization events (counts per minute) directly and as such, is withdrawn when power is starting to be produced. The intermediate range detectors, active up to ~25% power, are typically ionization chambers, where the neutron flux induces a current in the detector circuitry. These are also withdrawn before full power operations begin.

The local power range monitor (LPRM) is a set of fixed in-core proportional detectors to measure local neutron flux at various radial and four axial in-core locations. The instrumentation tubes, in which the LPRMs are housed, are long sheaths, permanently fixed from the bottom of the reactor vessel into the region between selected fuel assemblies. The LPRMs are fixed in these instrumentation tubes along with a pathway for a movable detector. The LPRMs are periodically calibrated using the traversing in-core probe system (TIP), which is sensitive either to the neutron flux or gamma flux. This system is capable of finely spaced axial flux measurements and the shape of the flux is used to calibrate the LPRMs within an axial instrument string, and also across the radially spaced instrument strings.

During normal operation, the LPRMs are used to monitor reactor thermal power and the overall core power distribution. Signals are used by the average power range monitoring (APRM) system and rod block monitors. In addition, detailed assembly power distributions are determined, both by TIPs and by LPRMs.

Reactor startup

A BWR follows basically the same "countdown" procedure as a PWR, with some specific differences outlined in [Table 2](#). In particular, reactor heatup and pressurization are achieved primarily by nuclear heating, as opposed to heating only by reactor coolant pumps. Therefore, during much of the startup evolution, the reactor is not in "shutdown" mode in the sense that it is subcritical.

Table 2 Typical BWR modes for startup.

Mode	Title	Reactor mode switch position	Average reactor coolant temperature (F)
1	Power Operation	RUN	NA
2	Startup	Refuel or startup/hot standby	NA
3	Hot Shutdown	Shutdown	> 200 °F (93°C)
4	Cold Shutdown	Shutdown	≤ 200 °F (93°C)
5	Refueling	Shutdown or refuel	NA

The startup evolution begins from the point when the core has been refueled, and the reactor vessel has been resealed. The vessel has been partially filled with water (typically to just below the steam line). The recirculation pumps are off, and the RHR pumps are aligned to remove core decay heat.

Heatup and power ascension

The reactor mode switch is placed in STARTUP, source range (SRM) and intermediate range (IRM) monitors are inserted, and control rods are pulled in a predefined sequence. As rods are pulled, source range counts and reactor period are monitored. As criticality is approached, it takes longer and longer to return to steady state after notching a rod. Eventually the reactor period will stay on scale between 50 and 300 s with no rod motion and counts will be continuously increasing. This is the point of criticality.

After the reactor is critical, a positive reactor period is established to raise power to the heating range. The power increase continues until heating power is reached. At this point control rod withdrawal is governed by the heatup rate, usually about 90 °F (50 °C) per hour. This heatup rate is a procedural limit. The Technical Specification limit is 100 °F (55.5 °C) per hour. Control rod withdrawal is constrained to an approved sequence such that control rod positions remain symmetrical and the reactivity worth of a given rod is minimized.

Shortly after, the point of adding heat is reached. This is when the nuclear heat from the fuel is greater than ambient losses from the system. The fuel warms up, the moderator temperature increases, and reactor period and power stabilize.

Once the point of adding heat is reached, rods will continue to be withdrawn to achieve heating power. Once boiling starts, the reactor head vent is closed, the main steam header equalizing valve and MSIVs are opened, the steam plant begins warming. Around 230 °F (110 °C) the steam drains are opened to de-aerate the reactor. Power ascension continues to produce sufficient steam to warm other components including the turbine.

As reactor water temperature increases, the coolant expands, causing the water level in the reactor vessel to increase. In order to maintain a constant level during heatup, water must be removed from the reactor vessel. The reactor water cleanup system (RWCU) is aligned to reject water to the main condenser or to the Liquid Radwaste system. It is usually more desirable to reject the excess water to the condenser in order to minimize the water processing load on the Liquid Radwaste system. This evolution continues until rated temperature and pressure are reached.

As temperature increases above 212 °F (100 °C) the reactor vessel begins to pressurize. At about 100 psig (0.68 MPa), the reactor core isolation cooling (RCIC) system and the high pressure coolant injection (HPCI) system, low steam pressure isolation is reset, and the steam lines to auxiliary steam loads such as reactor feedwater pump (RFP) turbines and steam jet air ejectors (SJAEs) are warmed. As pressure approaches 150 psig (1.14 MPa), the system pressure regulator begins to open bypass valves. To avoid bypassing steam to the main condenser and to allow plant pressurization, the pressure setpoint is increased to 920 psig (6.45 MPa). At about 350 psig (2.41 MPa), an RFP is started and placed in service. At about 450 psig (3.21 MPa), the SJAEs are placed in service to maintain a vacuum in the main condenser. Also at this time, the main turbine is reset and prepared for starting. As pressure reaches 920 psig (6.45 MPa), the bypass valves begin to open to control reactor pressure at the EHC system pressure setpoint. Control rods are withdrawn to increase power, which results in further opening of the bypass valves.

When power reaches 5–12%, the reactor mode switch is shifted to the “RUN” position (Mode 1), and the IRMs are fully withdrawn. Control rods continue to be withdrawn until 2–3 bypass valves are open, representing sufficient steam flow to roll the main turbine and provide minimum loading following synchronization to the grid. At about this time, the feedwater control system is placed in automatic.

Control rod withdrawal is used to increase power to approximately 60%. When approximately 60% power is reached, the control rods have been withdrawn to what is called a 100% or “target” rod pattern. This rod pattern, in turn, yields 100% reactor power when recirculation flow is increased to 100%. The power increase from 60% to 100% is accomplished by increasing recirculation flow, which increases moderation, subsequently increasing the reactor power. The recirculation flow control system is aligned with the individual loop controllers in master manual control. Recirculation flow is then increased to near 100% with the master flow controller.

After the generator is synchronized to the transmission grid and producing a substantial output, reactor power output is changed to meet the grid system requirements by adjustment of control rod position, manual adjustment of reactor recirculation flow, or a combination of these two methods. Withdrawing a control rod reduces neutron absorption and adds positive reactivity. Reactor power then increases until the increased steam formation just balances the change in reactivity caused by the rod withdrawal. The increase in boiling rate tends to raise reactor pressure, causing the EHC system pressure regulator to open the turbine control valves sufficiently to maintain a programmed throttle pressure. When a control rod is inserted, the reverse effect occurs.

Full power operations

Operating strategies

Baseload operation

As with the PWR, constant, full power operation has been the desired operational mode for BWRs. Normal power operation, including adjustment to rapid load changes, is controlled by manual or automatic adjustment of reactor recirculation flow. Also, manual adjustments of control rods are used to shape core power distribution and can be used to change reactor power levels due to daily load requirements.

Load follow

Reactor power output can be varied over a power range of approximately 25% of rated power by adjustment of reactor recirculation flow, which maintains a near uniform power distribution. Reactor power change is accomplished by using the negative void coefficient of reactivity. In practice, power adjustments of 15% or so are managed by core flow alone. An increase in recirculation flow temporarily reduces the volume of steam in the core by reducing the steam void fraction. This addition of reactivity to the core causes reactor power level to increase. The increased steam generation rate then returns the steam volume in the core to approximately its original value, and a new constant power level is established. When recirculation flow is reduced, reactor power is reduced in a similar manner. During initial power operation, the operating curve or power/flow map is established relating reactor power to recirculation flow. The first point of the curve is full flow and rated power. When a rod pattern is established for this point, recirculation flow is reduced in steps, at that rod pattern, and the relationship of flow to power is plotted for steady state conditions. Other curves are established at lower power ratings and other rod patterns as desired.

Flexible operation

Like for PWRs, flexible operation is essentially load follow, except that required response times are generally much shorter, and the times during which the reactor is at lower power can vary from a few hours to weeks. Flexible operation refers to operation responding to grid conditions that cannot be easily planned in advance. Such operation places additional stress on the fuel rods, unless operational constraints are observed, as discussed below.

To reliably operate the plant in this non-baseload condition requires a combination of fuel management strategies and power maneuvering guidelines, which have proven effective at significantly reducing the risk of pellet-cladding interaction (PCI) that may induce cladding failure during flexible operation (see also [Young, 2021](#)). Steps that are taken to prepare for such operation include managing the power levels on the fuel rods such that the stresses from the pellet on the cladding are given adequate time to relax. Guidelines for these preconditioning power levels and rates of power increase vary with the fuel type and fuel vendor. Following periods of extended low power operation, these guidelines assure that proper reconditioning to relax the stress in the fuel rod is obtained during the ascension to power. These guidelines are informed by both analytical models and by data from test reactors ([Young, 2021](#)). These methods also show that design features, such as barrier liner of the cladding or small amounts of material doping within the fuel pellet, can improve resistance to PCI, and allow for slightly more aggressive ramp rate limits ([Young, 2021](#)).

Economics of load follow operation in BWRs

The economics of load following in BWRs are similar to those in a PWR. Minimizing operating costs and fuel costs while maximizing annual power output are key to reducing the cost of nuclear electricity production for a specific reactor.

Surveillance

Normal operation

During normal operation, constant surveillance of the reactor power and its distribution is maintained (for additional details see Section 2.1). In addition, coolant samples are taken at regular intervals, and tested for the presence of various elements and radioisotopes. Generally these measured quantities fall into four categories and indications:

- (a) The purity of the circulating coolant is confirmed by monitoring coolant conductivity and pH.
- (b) Chloride levels are monitored to assure the mitigation of stress corrosion cracking of structural materials.
- (c) Oxygen, iron particulates, and silica are also monitored.
- (d) Fission products such as Iodine and Xenon are monitored. Large changes indicate the presence of leaking fuel rods.

Additional reactor monitoring during normal operation include:

- (e) Control rod drive testing: control rods are moved down and up a few steps, sufficient to confirm the control rod drive mechanisms are operational, without affecting the core power distribution significantly.
- (f) Calorimetric tests to confirm reactor power.

Reactor trips and restarts

The plant is designed to accommodate abnormal shutdowns such as loss of generator load or turbine trip. Depending on the operating condition of the plant and size of the load rejection, a portion of the steam may be bypassed to the condenser. When the

bypass system is not capable of accommodating the excess steam generation, the reactor will automatically scram and the reactor isolation cooling and HPCS systems will be actuated, if required to maintain the vessel water level. Any of the foregoing shutdown modes of operation may be established after the emergency shutdown.

The normal plant operating features that delay achieving power following a scram are:

- Control rod withdrawal rates
- Cold plant heatup rates
- Turbine loading rates
- Xenon considerations

The exact recovery time, dictated by rod removal rates, is a function of elapsed fuel cycle time. At the beginning of the cycle, a shorter time could be realized, but toward the end of the fuel life, more control rods must be removed to reach power and a longer time is required.

Constraints are imposed on the rate of power increase to ensure that prior to a fuel failure threshold being reached (a PCI limit), the induced stress is relieved, or that the release of corrosive fission products from the fuel is sufficiently slow to prevent reactive chemical species traveling from the release site in the fuel to the cladding, and chemically attacking the inner-surface, causing embrittlement. The impact of these constraints on load follow operation is discussed further in (IAEA, 2018). The physical process in the fuel rod during power changes is described further in (Young, 2021).

The fuel rod local power density has threshold values, generally as a function of burnup and residence time in the reactor, below which rates of power change are not constrained. These are implemented generally as either absolute power levels (and rates of change of power), or in terms of a calculated stress level. Lower values apply to fuel that has experienced sustained control rod insertion or sustained operation at low power; this is termed the conditioned power level of the fuel. Above these thresholds, power ramp rates (and step changes in power) are constrained.

If the reactor systems are to be cooled down, a heating rate may be the limiting factor based on temperature differences existing in particular regions of the pressure vessel. The turbine loading rates are a function of the turbine temperature.

Reactor shutdown for refueling

A plant shutdown is accomplished by essentially reversing the steps described for startup and power operation.

Preparation for plant shutdown involves testing of systems required to maintain cold shutdown and other equipment checks such as the turbine oil systems, flushing of the RHR system (shutdown cooling piping).

Reactor power is reduced from 100% to approximately 60% by using the recirculation flow control system. This requires adjusting the master flow controller to reduce recirculation pump speed to minimum. Control rods are now inserted in reverse of the withdrawal sequence to obtain a reactor power of approximately 10%. At this time, the IRM detectors are inserted, and the reactor mode switch is transferred to the startup position. Generator load is reduced to a minimum and the turbine generator is separated from the transmission system. Turbine steam flow is picked up automatically by the bypass valves. Control rod insertion continues until all rods reach the full in position. Reactor cooldown is commenced by withdrawing steam from the reactor via the bypass valves and maintaining vessel inventory using a reactor feed pump. A cooldown rate of 90 °F (32 °C)/hr. is established. When reactor pressure has been reduced to approximately 50 psig (0.35 MPa), the shutdown cooling mode of the RHR system is initiated and is used to cool the nuclear system down to a temperature of 150 °F (66 °C). The reactor shutdown is essentially complete. Some plant shutdowns may require flooding of the reactor vessel. This is normally done using a condensate pump and would be necessary if the plant was going into refueling operations.

Reactor disassembly and refueling operations

In order to refuel, the reactor must be disassembled. After reactor shutdown and during cooldown, the reactor pressure vessel is vented and filled to above the flange level to promote cooling. The drywell head cavity is drained and drywell head bolts removed during this time in preparation for head removal.

The drywell head typically utilizes swing bolts, which are loosened to clear the head and swing outward to lean on the reactor well wall. The unbolted drywell head is lifted by the polar building crane to its storage place on the refuel floor. The drywell seal surface protector is installed before any other activity proceeds in the reactor well area.

With the drywell head removed, an array of piping is exposed that must be serviced. Various vent piping penetrations through the reactor well must be removed and the penetrations made water tight. Vessel head piping is stored on the head insulation and a common lift is used to transport them to storage on the refueling floor.

Water level in the vessel is now lowered to the flange level in preparation for reactor vessel head removal. Using a strongback and the reactor building crane, the reactor vessel head is removed to the head holding pedestals on the refueling floor, keeping the vessel head elevated in order to facilitate inspection and O-ring replacement. If necessary, the vessel studs in line with the transfer canal are removed to provide a path for fuel movement.

The dryer is lifted via strongback and reactor building crane to its storage location. Prior to removal of the steam separators, the steam line plugs are installed in the main steam line nozzles from inside the vessel. With these plugs in place, servicing of the safety/relief valves or main steam isolation valves can be accomplished without interference or holdup due to refueling activities.

The separator is unbolted and unlatched from the shroud. With strongback and the reactor building crane, the separator is lifted and transferred underwater to its storage location in the pool.

The gate isolating the fuel transfer area is removed, connecting the reactor well and the fuel transfer area. The refueling platform is the principal device to handle and transfer the fuel assemblies in and out of the reactor. To move fuel, the grapple is aligned over the fuel assembly, lowered and attached to the fuel bundle bail handle. The fuel bundle is raised out of the core and moved through the refueling slot, positioned over the storage rack and lowered into the rack. Fuel is shuffled to respective new locations for the coming fuel cycle, and then new fuel is moved from the storage racks to the reactor vessel in the same manner.

Plant activities during the refueling outage

As in the PWR, a refueling outage at a BWR represents a critical time period for performing equipment inspection, maintenance, and replacement. A similar level of activity over a short period of time takes place at a BWR.

Reactor re-assembly and startup

Reactor assembly, following the refueling outage, is essentially achieved by reversing the operations described in the beginning of this section. Startup then proceeds as described at the beginning of this section.

Glossary

Burnup The amount of energy generated per unit mass of fuel. Usually expressed as megawatt-days per metric ton of uranium. The amount of fission products in the fuel is directly related to the burnup of the fuel.

Control element A component of a reactor that is controlled by the operator to affect the reactivity of the core. A common control element is a control rod that contains a neutron absorbing material such as boron that can be inserted or retracted from the core.

Cross section A material property that measures the probability of an interaction, such as neutron-induced fission. Reaction rates, such as the fission rate, are proportional to the neutron flux and the fission cross section of the material.

Crud A colloquial term for corrosion and wear products (rust particles, etc.) that become radioactive (i.e., activated) when exposed to radiation ([Nuclear Regulatory Commission, 2020](#)).

Deterministic method A method to non-randomly calculate the neutron flux and reaction rates by numerically solving the neutron transport equation. Contrast with the Monte Carlo method.

Fissile A nuclide is considered fissile if a neutron with zero kinetic energy can induce fission in the nucleus.

Fission product A nuclide produced when another nucleus breaks apart during nuclear fission. Some examples are Strontium-90, Cesium-137, Xenon-135, and Iodine-131.

Fissionable A nuclide is considered fissile if fission can be induced by a neutron with high kinetic energy (a fast neutron).

Fluence Total number of neutrons that have crossed a unit area; equal to the integral of the flux over time. Usually used in the context of material damage. Units of neutron flux are neutrons per square centimeter.

Flux spectrum The energy dependence of the neutron flux.

Flux The number of neutrons crossing a unit area per second. Reaction rates, such as the fission rate, are proportional to the neutron flux. Units of neutron flux are neutrons per square centimeter per second. The angular flux includes the dependence on neutron direction, and the units include solid angle in the denominator.

Moderator A material used to slow down the fast neutrons that are born from fission to a lower energy where there is a higher probability of causing fission.

Monte Carlo method A stochastic method to calculate neutron flux and reaction rates based on random sampling of known probability distributions of physical processes.

Neutronics The study of neutron transport within a reactor.

Nuclear resonance A large peak in a nuclear cross section at a particular incident neutron energy.

Nuclide A species of nucleus with a particular number of protons and neutrons (e.g., a Uranium-235 nucleus has 92 protons and 143 neutrons).

Reactivity worth The change in reactivity due to a specified change in the core (e.g., reactivity worth of a control element).

Reactivity Typically denoted by the symbol ρ , the reactivity represents the extent of the deviation in the core effective multiplication factor (usually denoted as k_{eff}) from its value at a just critical state (at which state $k_{\text{eff}} = 1.0$ and the fission rate is constant). A positive (negative) reactivity feedback implies that the ratio of the rate of neutron production to the rate of neutron losses (k_{eff}) is larger (smaller) than 1.0 due to a change in a performance characteristic such as temperature or density.

Shutdown margin The amount of reactivity by which the reactor is subcritical when all control elements have been inserted. The shutdown margin usually assumes that the control element with the highest worth remains fully withdrawn.

Subchannel The region of coolant in between fuel elements. This is usually a repeatable unit and forms the basis of most thermal hydraulic analysis.

Thermal feedback The impact of temperature change on reactivity, through mechanisms such as Doppler broadening of nuclear resonances in the fuel or changes in moderator density.

Thermal hydraulics The study of heat transfer, fluid mechanics, and thermodynamics needed to determine the temperature inside a nuclear reactor.

Validation The process of ensuring that a computer simulation or analysis method produces a result that is consistent with physical experiments.

Introduction

Other chapters (Hamon, 2021; Young, 2021a) discussed some of the general design and operations considerations for safe and reliable operations of nuclear reactors. This section will discuss some of the mathematical and computational methods that are used for the quantitative analysis of nuclear reactor core design and operations.

From a basic perspective, reactor design has two objectives. Number one is to always ensure the safety of the reactor under any condition, and number two, always behind safety considerations, is to produce power in an economical fashion.

To ensure safety, there are a few main considerations:

- The fuel and cladding temperatures need to stay within the design limits such that they do not melt or fail in any way.
- The reactor should be stable and have inherent passive negative thermal feedback (moderator temperature coefficient, fuel temperature coefficient, core expansion, etc.).
- Active control elements should be able to shut down the reactor under any conditions (i.e., have sufficient shutdown margin), and failure or loss of a control mechanism should not be harmful (e.g., rod ejection reactivity worth).

From an economical point of view, the main factors are:

- The reactor should operate at the maximum possible power for the longest amount of time (power $\times$ time = money).
- The reactor should be as neutronically efficient as possible to use least amount of input fuel as possible to save money on refueling costs.

Very often, these objectives may conflict with each other. For example, the most neutronically efficient core is one with most of the power in the center, and thus a low leakage of neutrons from the core. This, however, will have a very high local power in the center (peaking factor), which would raise the fuel temperature there to unacceptable levels.

Multi-physics computational methods: General considerations for multi-physics coupling

The core design and analysis is fundamentally a multi-physics problem, generally consisting of:

- Neutronics methods to calculate power distributions and reactivity within the core, and neutron fluence that may dictate long-term material damage in the pressure vessel, for example.
- Thermal hydraulics methods to calculate heat transfer and temperature distributions within the fuel and coolant.
- Materials, thermo-mechanical, and structural analysis methods to calculate the effect of temperature distributions, coolant induced vibrations and erosion etc. on the physical materials in the system.

Fig. 1 The process for the standard method to solve the coupled neutronics/thermal-hydraulics problem.

While the thermo-mechanical aspect can sometimes be ignored, or at least not included in all analyses, there is a fundamental and strong feedback between neutronics and thermal-hydraulics that must always be considered. The temperature of the system (fuel, coolant/moderator, etc.) affects the reactivity, which in turn affects the power level, which then affects the temperature again.

In theory, it is possible to create a set of equations governing the neutronics and thermal hydraulics and solve them as a single coupled system, such as in the MOOSE code system (Gaston et al., 2009). In practice, for large systems, this is a challenging problem, and not usually necessary. The standard approach is to solve each problem independently, and couple to each other. This process is outlined in Fig. 1. A temperature distribution, $T_0(\vec{r})$, is assumed. The neutronics problem is solved to obtain a power distribution, $P(\vec{r})$, and reactivity, ρ . The power distribution is input to a thermal-hydraulics solver, which will solve for the temperature distribution. If necessary, the temperature can be fed back into the neutronics solver until converged.

Neutronics computational methods

The full-scale direct solution of the stand-alone, steady-state neutron transport problem (Tsvetkov, 2021) is extremely challenging, even disregarding thermal feedback. In order to balance the accuracy needed for safe and economical operation with the speed required for everyday operational and design use, the industry has generally settled on the “two-step” computational approach for core neutronics:

1. Detailed (in space, energy, and angle) neutron transport solution for a set of simplified 2D problems (e.g., pin cell or single fuel-assembly), and generation of homogenized group constants.
2. Use of the homogenized group constants in a coarse spatial mesh 3D core model, using relatively few energy groups and simplified angular dependence (usually the diffusion approximation).

The proper generation of group constants using the full neutron transport solution generally ensures good accuracy for the quantities of interest (eigenvalue, reaction rates), while the coarse 3D solution can be obtained fairly quickly (usually less than 1 s).

Nuclear Data

The fundamental nuclear data required for reactor calculations include:

- Point-wise (continuous energy) neutron cross-sections for all reactions of interest.
- Resolved and unresolved nuclear resonance parameters for important nuclides.
- Fission product yield data for all fissile and fissionable nuclides.
- Decay constants (half-lives, decay products, branching ratios) of fission and transmutation products.

There are several sources of this data available, which include:

- US-developed Evaluated Nuclear Data File Version B (ENDF/B) (Brown et al., 2018).
- European Joint Evaluated Fission and Fusion Library (JEFF) (Koning et al., 2011).
- Japanese Evaluated Nuclear Data File (JENDL) (Shibata et al., 2011).
- Russian Library of Evaluated Neutron Reaction Data (BROND) (Blokhin et al., 2016).
- Chinese Evaluated Nuclear Data Library (CENDL) (Ge et al., 2017).
- TALYS-based evaluated nuclear data library (TENDL) (Koning et al., 2019).

Additional information on the selection and use of nuclear data sets can be found in other documentation such as ANSI/ANS 19.1-2019 (American Nuclear Society, 2019).

Multi-group (application-dependent) cross sections

The most important nuclear data is the nuclear macroscopic cross section $\Sigma(E)$, which represents the probability per unit length of particle travel that a nuclear reaction will occur. The macroscopic cross section is calculated as the microscopic cross section $\sigma(E)$

times the number density of a given nuclide. The neutron flux and neutron cross section can be used to calculate the reaction rate density:

$$R \left[\frac{\text{reactions}}{\text{cm}^3 \text{ s}} \right] = \int_0^\infty dE \Sigma(E) \phi(E)$$

In a nuclear reactor, neutron energies can vary from around 0.01 eV to 10 MeV. Cross-sections have a strong dependence on energy, and can vary by many orders of magnitude at local nuclear resonances. For a more thorough discussion of neutron flux, cross-sections, and reaction rates, the reader is directed to [Tsvetkov \(2021\)](#).

Most neutron transport solvers, with the exception of Monte Carlo-based solvers, cannot use continuous energy cross-sections directly, and require the use of multi-group cross-sections. In general, a multi-group cross section for energy group g , Σ_g , can be written as a function of the continuous energy cross section $\Sigma(E)$, and a weighting flux spectrum $\phi(E)$:

$$\Sigma_g = \frac{\int_{E_g}^{E_{g+1}} dE \phi(E) \Sigma(E)}{\int_{E_g}^{E_{g+1}} dE \phi(E)}$$

Since the weighting flux spectrum should logically vary between reactor types, all multi-group cross section libraries are inherently application-dependent, and care must be taken in their use. In general, the more energy groups in the multi-group library, the less impact there is on the accuracy of the weighting flux. There are various methods for determining the weighting flux spectrum, which may assume homogenous or 1D geometry. There are many computer codes in common use to perform this multi-group cross-section generation. These include BONAMI ([Greene, 1984](#)) and CENTRM ([Williams et al., 2007](#)) for LWR applications and MC2-3 ([Lee and Yang, 2017](#)) for fast reactor applications.

The number of energy groups used in the multi-group cross section libraries varies significantly with the application. In general, fast spectrum reactor problems require many more than thermal reactor problems. Light water reactor libraries are generally in the 10s to 100s of energy groups, while liquid metal fast reactors may use 1000s to 100,000s of energy groups. This initial simplified-geometry cross-section generation process is usually followed by lattice physics calculations on a more representative geometry to further reduce the number of energy groups.

Lattice physics calculations

Given an application-dependent set of multi-group cross-sections, the goal of lattice physics calculations are to homogenize (i.e., remove the spatial dependence), and perform energy condensation (reduce the number of energy groups) to allow for accurate and fast full-core calculations. This is usually done by solving the transport equation for the multi-group flux on a single fuel assembly (or lattice) with reflective boundary conditions in 2D geometry. When the multi-group flux $\phi_g(\vec{r})$, has been solved for in the lattice, homogenization and group condensation is performed on the basis of preserving reaction rates in the homogenized cell (such as a fuel assembly as shown in [Fig. 2](#)).

Fig. 2 Assembly lattice homogenization for two fuel assembly types.

The homogenization process to obtain the homogenized cross-sections $\bar{\Sigma}_g$, based on the preservation of reaction rates over the volume of the cell V_{cell} is given by:

$$V_{cell} \bar{\phi}_g \bar{\Sigma}_g = \int_V dV \phi_g(\vec{r}) \Sigma_g(\vec{r})$$

The cell averaged group g flux over volume V_{cell} is defined as:

$$\bar{\phi}_g = \frac{1}{V_{cell}} \int_V dV \phi_g(\vec{r})$$

Starting with G energy groups, it is also possible to reduce this to smaller set of groups H , called a broad-group or few-group cross-sections $\bar{\Sigma}_h$. This is process, called energy collapsing or condensation, is based on preservation of reaction rates as given by:

$$\bar{\phi}_h \bar{\Sigma}_h = \sum_{g \in h} \bar{\phi}_g \bar{\Sigma}_g$$

One challenge with the spatial homogenization process is that local properties such as the pin-wise power distribution are lost. It is possible, however, to recover this information in a process known as pin-power reconstruction (Koebeke and Wagner, 1977; Rempe et al., 1989). This is generally done by multiplying the flux calculated in the full-core homogenized medium by a pin-wise form function obtained during the lattice calculation, as shown below (Rempe et al., 1989).

$$\phi_g(xy) = \phi_g(xy)_{homogenous} \times \phi_g(xy)_{form\ function}$$

Pin power reconstruction is important because it is needed to determine the local power needed for thermal and safety analysis. An example of a pin power distribution in a typical pressurized water reactor (PWR) assembly is shown in Fig. 3, which was calculated based on the geometry in Fig. 2. The power is higher near the guide tubes where there is additional moderator present.

While the homogenization process aims to preserve the transport solution as much as possible, there are errors introduced in this approximation when applied to the full-core solution. For one, there must be an assumption made for the boundary conditions during the lattice calculation, which is generally considered reflective. This is, of course, not true in the real core, and the assembly may be greatly affected by nearby dissimilar assemblies. The reaction-rate preserving homogenization process also does not necessarily preserve the current at the assembly boundary. There are two general approaches to increase the accuracy of the homogenized result: Generalized Equivalence Theory (Smith, 1986) and the Super Homogenization (SPH) method (Hébert and Benoist, 1991). Homogenization is an important but challenging process, with many subtle details that may affect the result. Research is ongoing in the area to improve the accuracy (Smith, 2017).

Fig. 3 Normalized pin-power distribution calculated for a sample pressurized water reactor lattice.

Lattice physics methods

The calculation of the flux in the fuel lattice can be accomplished using a variety of lattice physics methods. The neutron flux is generally a function of space, angle (or direction of travel), and energy (or velocity). Lattice physics methods must have high fidelity in all these variables in order to accurately calculate the neutron flux needed for homogenization.

The discrete ordinates (or Sn) method is a deterministic method based on the differential form of the neutron transport equation, and solves for the angular flux along a set of discrete directions (ordinates), on a spatial mesh. This method is not as popular for lattice physics problems due to the extremely small spatial mesh size that is usually required for accurate solutions. The NEWT code (DeHart and Bowman, 2011) in the SCALE package is an example of a discrete ordinates lattice physics code.

The Method of Characteristics (MOC), and Collision Probability (CP) deterministic methods are based on the integral form of the neutron transport equation. They attempt to solve the equation along a set of characteristic rays. These have the advantage that they can better handle the curved geometry of fuel rods using fewer variables. Examples of MOC codes include HELIOS (Wemple et al., 2008), POLARIS (Jessee et al., 2014), CASMO (Rhodes et al., 2006), and APOLLO (Sanchez et al., 2010). Some CP codes include PARAGON (Matsumoto et al., 2006) and DRAGON (Hébert, 2016).

Monte Carlo methods solve the transport problem by following randomly sampled neutrons statistically through a probabilistic representation of each component of the transport equation until the neutron's termination by absorption or leakage from the system. These techniques have gained popularity for few-group cross section generation in recent years, due to increased computational power, and the fact that they can use continuous energy cross sections directly, without the need for problem-dependent multi-group cross-sections. Monte Carlo methods also do not suffer from spatial and angular discretization errors, which can be a challenge with deterministic codes. The main disadvantage of Monte Carlo is that it is a stochastic method with inherent statistical uncertainty and can require longer computation time to reach an acceptable level of uncertainty. Monte Carlo codes currently in use for few-group cross section generation include Serpent (Leppänen et al., 2015), KENO (DeHart and Bowman, 2011), and OpenMC (Romano et al., 2015).

Depletion calculations

Along with generation of group constants and few-group cross-sections, the other task of lattice physics codes is to perform depletion calculations. This process requires the tracking of changes in number density for all nuclides, as well as the resulting changes in cross-sections. Many different reactions must be tracked that account for loss and production mechanisms for each nuclide.

Loss mechanisms for a given nuclide include:

- Any non-scattering (i.e., absorption) reaction: (n, γ) , (n, f) , (n, xn) , (n, p) , (n, α) , etc.
- Radioactive decay.

Production mechanisms include:

- Direct production from fission.
- Transmutation from another nuclide (usually n, γ).
- Radioactive decay from parent nuclide.

Putting these together, one generally arrives at a rate-of-change equation for every nuclide in the system resembling the one below:

$$\frac{dN_x}{dt} = \gamma_x N_f \sigma_f \phi + N_y \sigma_{\gamma} \phi + \lambda_p N_p - \sigma_{a,x} \phi N_x - \lambda_x N_x$$

Where,

- $\gamma_x N_f \sigma_f \phi$ is production of nuclide x from fission;
- $N_y \sigma_{\gamma} \phi$ is the transmutation of nuclide y into nuclide x;
- $\lambda_p N_p$ is the radioactive decay of nuclide p into nuclide x;
- $\sigma_{a,x} \phi N_x$ is the transmutation of nuclide x from neutron absorption;
- $\lambda_x N_x$ is the loss rate of nuclide x from radioactive decay.

There are a few challenges with this approach. First is the cross sections σ_f , σ_{γ} , and $\sigma_{a,x}$ which are one-group cross sections. Since they are only one energy group, they will vary significantly as the neutron spectrum changes throughout the operating cycle. This necessitates recalculating these cross sections fairly often with fuel burnup. Second is the sheer number of nuclides that must be simulated. Depending on the application, this is usually in the hundreds. The compositions vary spatially, in which case hundreds of nuclides must be tracked throughout hundreds (or millions) of different zones. Lattice physics codes automate this depletion process, and a variety of mathematical methods have been used to solve the basic depletion equations.

Few-group cross section parameterization

The depletion calculations are normally performed at nominal conditions (e.g., like fuel temperature, moderator temperature, boron concentration). At several points in the depletion calculations, branch calculations are usually performed at off-nominal

conditions in order to determine the dependency of the group constants on reactor conditions. Branch calculations are a set of calculations done at high and low values of certain parameters (such as fuel temperature, moderator density, boron concentration). It is then possible to estimate the cross-sections for any combination of these conditions at a given burnup. For example, the cross section representation in PARCS (Downar et al., 2002) for a PWR system is considered as follows:

$$\Sigma(\alpha, T_f, T_m, \rho_m, N_b) = \Sigma^r + \alpha \Delta \Sigma^{cr} + \frac{\partial \Sigma}{\partial \sqrt{T_f}} \Delta \sqrt{T_f} + \frac{\partial \Sigma}{\partial T_m} \Delta T_m + \frac{\partial \Sigma}{\partial \rho_m} \Delta \rho_m + \frac{\partial \Sigma}{\partial N_b} \Delta N_b + \frac{\partial^2 \Sigma}{\partial \rho_m^2} (\Delta \rho_m)^2$$

Where,

- Σ^r is the cross section at nominal conditions
- α and $\Delta \Sigma^{cr}$ are factors accounting for the control rods being present or not in the region
- ΔT_f is the difference in fuel temperature from nominal conditions
- ΔT_m is the difference in moderator temperature from nominal conditions
- $\Delta \rho_m$ is the difference in moderator density from nominal conditions
- ΔN_b is the difference in boron concentration from nominal conditions
- The derivatives such as $\frac{\partial \Sigma}{\partial T_m}$ are determined from the branch calculations (at high/low conditions away from nominal to calculate the derivative).

Additionally, other conditions may be considered for cross section parameterization, such as xenon concentration; or void history and control rod history, which both affect the spectral conditions and thus also the composition of the fuel at a given burnup level (Baturin and Vygovskii, 2001).

Core simulation

Given the few-group cross-sections, parameterized by all the factors required for the given reactor type, the most common core analysis method are deterministic nodal diffusion methods. Speed of calculation is extremely important for core analysis, because many cases must be run. Since the composition of the fuel is constantly changing over a cycle, the core analysis code has to be run over many time-steps to account for this. Additional runs are also required for the criticality search to determine the level of reactivity control required to keep the reactor critical (e.g., critical rod position, critical boron concentration, etc.).

Nodal codes use a coarse representation of the angular variable, which is generally based on diffusion theory or simplified P3 (SP3). Diffusion theory considers that the angular flux only has a linear dependence on angle, and can break down in areas of high flux gradients. The P3 considers a third order Legendre polynomial expansion of the angular flux in the transport equation, while the SP3 method ignores many of the terms for a much simpler and faster solution (Brantley and Larsen, 2000).

Spatially, the core is divided into segments called nodes; typical node size is a quarter-assembly per node in the radial direction, and 24 nodes axially, although smaller nodes are possible. There is also some effort to perform pin-wise nodal calculation to increase the pin-wise accuracy. Some examples of nodal core calculation codes include: ANC (Liu et al., 1985), SIMULATE (Rempe et al., 1989), ARES (Leppänen et al., 2014), NESTLE (Turinsky et al., 1994), PANACEA (Chiang et al., 1985), PANTHER (Hutt et al., 1991), PARCS (Downar et al., 2002), DONJON (Hébert, 2016), and REBUS/DIF3D (Collins et al., 2016). Most nodal codes can perform a single core calculation on a single CPU in fractions of a second.

Although nodal diffusion has been the workhorse of the nuclear industry for decades, there has also been some effort to develop higher-fidelity whole-core analysis codes based on transport theory. These codes generally use hundreds of energy groups and much higher spatial and angular resolution than nodal codes. Although this can increase the accuracy, especially for pin-resolved results, it comes at a very high computational cost. Deterministic whole-core transport solvers are typically run on thousands of CPUs, and may take minutes-hours-days of computation time. This makes it difficult to use for routine analysis and design, but can be used in special cases. Some examples of high-fidelity transport codes for full-core analysis are MPACT (Collins et al., 2016), nTRACER (Jung et al., 2013), and DeCART (Joo et al., 2004).

The Monte Carlo method is the most accurate method for reactor physics, since it does not require discretization in space, energy, or angle, unlike deterministic methods. However, it suffers from statistical uncertainty, especially if local results (like pin-power) are required. For whole-core analysis, this requires the simulation of billions or more particles. Although computational speeds have increased over the years, this is still a very challenging prospect, especially for routine calculations. Generally Monte Carlo methods are mostly used occasionally as “reference” solutions to make sure that the everyday deterministic methods are working well. Some of the most prominent Monte Carlo codes that have been used for core analysis include MCNP (Goorley et al., 2012), Serpent (Leppänen et al., 2015), KENO (DeHart and Bowman, 2011), Shift (Pandya et al., 2016).

Loading pattern development

Typically, most power reactors around the world operate on a 12, 18, or 24 month cycle. Some reactors, such as CANDU reactors (Nichita, 2021), the fuel is shuffled almost continuously. In molten-salt reactors, the fuel is homogenous, and there can be a near-continuous removal of spent fuel and addition of fresh material. Generally, however, at the end of every cycle, the reactor shuts down, some fraction of the fuel assemblies are removed (typically around 1/3), and a corresponding number of fresh assemblies

are added. Where in the core to place the new and old assemblies for the next cycle, as well as the properties of the incoming fresh fuel, is called a loading pattern. This pattern is of critical importance, as it will determine the safety and efficiency of the system. As with most things, the goals are to maximize fuel efficiency (at the economic concerns) while staying within important safety constraints. Specifically, one usually wants to:

- *Minimize neutron leakage* from the core to maximize neutron efficiency. This can be done by putting low-enriched or highly-burned fuel towards the radial edge of the core. Increased neutron efficiency will allow for either a longer cycle length before refueling, or require fewer fresh assemblies to be loaded. Reduced leakage also has the benefit of reducing the neutron fluence to the pressure vessel, which is the lifetime-limiting factor for many reactor designs.
- *Minimize power peaking* in the core to keep local power within safety limits. Since a reactor is usually operated to run at a given average power, any power peaking means a higher local power. Reactor safety is limited by the ability to keep the hottest part of the reactor cool, so a high peaking factor would require a lowering of the average power to keep the peak power below the limit. Limiting power peaking can be done by putting fresh and burned assemblies in a checkerboard pattern, and by putting some higher-reactivity assemblies near the core periphery.
- *Stay within all other safety constraints*, which may include reactor control shutdown margin, the worth of the highest worth control rod in the case of a rod-ejection accident, reactivity coefficients, etc.

Unfortunately, these objectives are usually conflicting in nature, and optimization is challenging. The most efficient type of core neutronics is low-leakage with high-reactivity in the middle and low-reactivity on the periphery. However, that is also the worst from a power peaking point of view, as all the power will be concentrated in the center of the core.

Several example core loading options are shown in Fig. 4 (Tsoulfanidis, 2013). The Out-In pattern is very simple: fresh fuel is loaded on the outside of the core, and subsequent batches are moved to towards the middle, and then removed. This results in power peaking towards the edge of the core, but still has relatively less peaking than a uniform core or one loaded with the fresh fuel in the middle. One modification to this is the checkerboard loading, yields very low power peaking. Both of these loading patterns, however, have a high amount of leakage which is bad for neutron economy and pressure vessel damage. One slight modification can be obtained with a low leakage core loading, in which low-reactivity fuel is placed on the periphery, fresh fuel just inside of that, and a mixture of fuel in the middle. The ring of fresh fuel helps to draw power to the outside to help with power peaking, while the low reactivity fuel at the periphery reduces the leakage. Radial power distributions for uniform, checkerboard, and low-leakage core loading patterns are shown in Fig. 5. The low leakage pattern increases power peaking slightly while significantly reducing neutron leakage.

The traditional method of core loading optimization is manual, relying on trial-and-error and engineering judgment. This can certainly be successful, but requires years of core design experience and can be difficult to teach. It is also prone to personal preference and biases, and the overall design space that is explored will likely be very small.

There are several automated algorithms that are available, which due to the automated nature can explore a much larger design space, and do not rely nearly as much on personal judgment and years of expertise. This area has been well studied due to the cost savings that are possible (Levine, 1981; Yamamoto, 1997). The two most popular methods currently are genetic algorithms and simulated annealing.

Genetic algorithms are based on concepts from biological evolution. A semi-random set of possible initial layouts (the population) is evaluated, and the “best” candidates are taken forward to the next generation. A new population is created by combining aspects of the chosen candidates (crossover). Random mutations are also added to ensure the optimization does not get stuck in local minima. These algorithms have seen some success in core design, as demonstrated by Haibach and Feltus (1997) and Yamamoto (1997).

Simulated annealing is another optimization method widely used across many disciplines for problems with large solution spaces (Kirkpatrick et al., 1983). The fundamentals of simulated annealing are based on the concept of annealing in metallurgy. The algorithm starts with an initial random loading pattern. A perturbation is made to the layout, and the new layout is randomly accepted based on a combination of the fitness of the layout, and a “temperature” parameter. A high temperature parameter increases the change to move to a “worse” layout. The temperature starts out high, allowing many “worse” permutations, but avoiding getting stuck in local minima. As the algorithm progresses, the temperature is lowered (as in metallurgical annealing), and the

Fig. 5 Radial power distributions for uniform, checkerboard, and low-leakage core loading patterns.

Fig. 6 An illustration of the challenge of global optimization of a function in 1D.

algorithm hopefully settles onto a good solution. This method has been successfully applied by Westinghouse with their Shuffleworks code, the Studsvik code SIMAN (Stevens et al., 1995), and others (Kropaczek and Turinsky, 1991).

A key aspect of both of these methods, and in optimization of large complex problems, is avoiding solutions that appear to be locally optimal. That is, any *small* change will result in a worse system. However, the system may be better if some large changes are made. A simple example for a 1D optimization problem, finding the minimum of a function $f(x)$, is shown in Fig. 6. The local minimum on the left can look like a good solution to a simple optimization method (e.g., gradient descent), while missing the global minimum on the right. Simulated annealing avoids this by allowing large, unfavorable changes at the beginning. Genetic algorithms avoid this with both the mutation and crossover features.

Thermo-hydraulic computational methods

As discussed earlier, there is a strong connection feedback between neutronics and temperature distributions within the reactor. The above methods only solved the neutronics side, and generally thermal-hydraulics calculations are done to solve for the temperature distribution in the system for a given power distribution.

These methods must solve for:

- The mostly 1D radial heat transfer from the fuel, cladding, and fuel-cladding gap;
- Heat transfer into the coolant with turbulent flow and possibly various boiling regimes;
- Coolant flow properties (3D or approximated as 1D), and pressure drop through the core and secondary systems.

Fig. 7 Radial temperature profile in a nuclear fuel rod.

A typical temperature profile for 1D radial heat transfer in a fuel rod is shown in Fig. 7. This is characterized by a quadratic profile in the fuel where heat is being generated, a rapid drop in the fuel-clad gap due to the low conductivity, and a relatively small drop within the cladding. The profile within the coolant is generally quite complex.

An example of the temperature feedback on the power distribution in a PWR is shown in Fig. 8. A uniform temperature distribution results in a cosine-shaped axial power profile. Since most systems are designed to have negative moderator temperature

Fig. 8 Axial power distribution for a uniform temperature and with a downward shift due to cold inlet temperature (left); and the resulting coolant, fuel, and cladding temperatures (right).

feedback, cold coolant entering at the bottom will tend to push the power towards the bottom of the reactor. The resulting coolant, fuel, and cladding temperatures are also shown in Fig. 8.

Subchannel methods

Most reactor thermal analysis is done on the basis of the *subchannel*, which is defined as the area in between fuel rods, as shown in Fig. 9. The fluid state (e.g., temperature, density, velocity, pressure, vapor fraction) is not resolved within the subchannel, but instead taken as an average over the area. The 1D heat conduction equation can be solved radially, and then empirical correlations must be used to determine the turbulent heat transfer from rods to the fuel. Generally, changes in the axial flow direction will be resolved by considering multiple nodes in the axial direction. Conservation equations for mass, momentum, and energy are used for the fluid flow. In the case of two-phase flow, which is common in water-cooled reactors, these equations can be solved separately for the liquid, vapor, and entrained droplets.

In some cases, one may do an analysis for an “average” subchannel or “hottest” subchannel, in which case there is assumed to be no flow between adjacent subchannels (similar to the reflective boundary condition used in fuel assembly neutronics calculations), and only a single subchannel will be analyzed. If more fidelity is required, then all subchannels within an assembly, or the entire core, could be modeled. In this case, there will be cross-flow between adjacent subchannels, and a 3D result can be obtained.

Non-dimensional numbers and empirical correlations

Since the details of the fluid flow within the subchannels are not resolved, and only the bulk coolant properties are known, we must rely on empirical correlations to determine the heat transfer from the fuel rods to the coolant. These correlations are usually made on the non-dimensional numbers that characterize the flow conditions (primarily Reynolds, Prandtl, and Nusselt numbers). The use of non-dimensional numbers allows the correlations to be used in a wider variety of conditions than being limited strictly to the experimental conditions. Before discussing these non-dimensional numbers, it is useful to know the main dimensional parameters associated with these problems, as shown in Table 1.

The Reynolds number is the ratio of inertial forces to viscous forces, and effectively represents the effect of turbulence in the system. Viscous forces tend to damp out turbulence, so a high Reynolds number indicates a higher effect from turbulence.

$$Re = \frac{\text{Inertial forces}}{\text{Viscous forces}} = \frac{\rho u D}{\mu}$$

The Prandtl number represents the ratio of momentum diffusivity to thermal diffusivity, and is effectively a property of the fluid as it does not depend on any parameters of the system (e.g., diameter, velocity, etc.). The Prandtl number is very low (< 0.1) for

Fig. 9 Illustration of the subchannels for square pitch (left) and triangular pitch (right) fuel rods that are typically used for subchannel analysis.

Table 1 Some dimensional parameters associated with thermal fluid heat transfer problems.

Parameter	Symbol	Unit (SI)
Density	ρ	kg/m ³
Flow speed	u	m/s
Hydraulic diameter	D	m
Dynamic viscosity	μ	kg/(m · s)
Specific heat	c_p	J/(kg · K)
Thermal conductivity	k	W/(m · K)
Convective heat transfer coefficient	h	W/(m ² · K)

liquid metal coolants, since they have very high thermal conductivity and low viscosity. For water and gas coolants, the Prandtl number is around 1.

$$\text{Pr} = \frac{\text{Momentum diffusivity}}{\text{Thermal diffusivity}} = \frac{c_p \mu}{k}$$

The Nusselt number corresponds to the relative importance of convective and conductive heat transfer mechanisms.

$$\text{Nu} = \frac{\text{Convective heat transfer}}{\text{Conductive heat transfer}} = \frac{hD}{k}$$

Empirical correlations such as the Dittus-Boelter equation (Dittus and Boelter, 1930), which applies to forced convection with no boiling, can be used to estimate the Nusselt number (and thus heat transfer from the fuel rods to the coolant).

$$\text{Nu} = 0.0243 \text{Re}^{0.8} \text{Pr}^{0.4}$$

Numerous such correlations exist for a variety of parameters of interest (e.g., pressure drop) and possible flow conditions. Empirical correlations can and have worked very well in nuclear reactor thermal-hydraulic analysis. However, there are significant limitations. First, they are only valid for the experimental conditions in which they were obtained.

In two-phase systems, there is the addition of the void fraction, which represents the relative volume of the vapor phase to the total volume.

$$\chi = \frac{V_{\text{vapour}}}{V_{\text{vapor}} + V_{\text{liquid}}}$$

Two-phase flow

The liquid-vapor flow regimes that are prevalent in boiling water reactors present additional challenges. Depending on flow rates, void fractions, and other conditions, a variety of two-phase flow regimes are possible, which have very different properties and interactions between the phases (Rouhani and Sohal, 1983). Precise delineation between regimes is challenging, but some common regimes include bubble flow, plug flow, slug flow, churn-turbulent flow, and annular flow. These involve bubbles or droplets of various shapes and sizes, films, etc., and have very complex relationships. A discussion of these regimes can be found in Young (2021b). As with single-phase flow, conservation of mass, momentum and energy must be considered, but for both liquid and vapor phases. This should also include some accounting for the interactions at the interface (e.g., interfacial shear, heat transfer) between the phases. Several approaches are possible, with varying levels of complexity (Faya et al., 1979).

The simplest approach is the homogeneous equilibrium model: the fluid and vapor are modeled as a single mixture, with equations for continuity, momentum, and energy. This assumes that both phases flow at the same velocity, and are at saturated conditions.

Higher in complexity is the drift-flux model (Kataoka and Ishii, 1987), which still combines the two fluids into a single mixture, but supplements this with equations for the relative velocity between the two phases (i.e., the drift-flux). This allows for better accounting for interfacial phenomenon than the homogenous model, but at significantly less complexity than a full two-fluid model. Correlations and closure relationships can be made based on the flow conditions, which vary significantly throughout the core, and can be difficult to predict.

Liquid and vapor phases can also be considered separately, with their own conservation equations, as in two-fluid models. Some models, such as in CTF (Salko et al., 2015), consider three fields: vapor, continuous liquid, and droplets. For the two or three-field approaches, there must be terms for the interactions at the interfaces of the three phases. One such approach is the interfacial area transport method (Ishii et al., 2002), which derives a transport equation for the liquid-vapor interface. This can allow for mechanistic treatment of two-phase phenomenon such as bubble break-up and coalescence, as well as different types of bubbles such as cap and spherical.

Subchannel codes

Subchannel methods have been the workhorse of the nuclear industry, and many codes have been used over the years (Moorthi et al., 2018). These include:

- COBRA-TF, which has been adopted by the Consortium for Advanced Simulation of Light Water Reactors (CASL) (Kelly et al., 2017; Salko et al., 2015);
- TRACE/RELAP, which is used by the US Nuclear Regulatory Commission (USNRC) (Fletcher and Schultz, 1992; Odar et al., 2003);
- VIPRE, sponsored by the Electric Power Research Institute (EPRI), approved by the USNRC, and widely used by US utilities (Srikantiah, 1992);
- COBRA-FLX, developed by AREVA (Bhatt et al., 2015).

Computational fluid dynamics methods

As discussed above, subchannel methods with empirical correlations have limitations, especially when it comes to predictive capabilities for new systems, and calculation of complex, 3D flows.

As an alternative, computational fluid dynamics (CFD) methods try to solve the Navier-Stokes equations that govern fluid flow to obtain the locally resolved fluid properties. Although there are several levels of detail that can be resolved in CFD, all methods require many orders of magnitude more unknowns than traditional subchannel or lumped-parameter methods. As such, they are generally too computationally expensive for most design problems at the industry level on desktop systems. Most examples of CFD for nuclear applications are for research or benchmarking, and require large-scale supercomputers.

There are many ways to solve the Navier-Stokes equations, with varying levels of complexity. The major distinguishing factor between methods is how turbulence is modeled, which has a significant impact on computation cost and accuracy. In decreasing order of computational cost, some of the major methods are summarized below:

- Direct Numerical Simulation (DNS) (Merzari et al., 2020; Tiselj et al., 2020). The Navier-Stokes equations are solved directly without additional models for turbulence. This requires an extremely small spatial mesh, down to the smallest eddy size, along with a corresponding short time-step. This method is impractical except for extremely small problems.
- Large-Eddy Simulation (LES) (Merzari et al., 2020; Tiselj et al., 2020). This method has a larger mesh size than DNS, and only spatially resolves the “large” eddies in the problem. Since the smaller, unmodeled turbulence still causes energy dissipation, a sub-grid model is needed to account for them.
- Reynolds-averaged Navier-Stokes (RANS). This method involves taking an ensemble averaging approach to the equation, which allows for larger mesh sizes than LES, but requires more assumptions about the underlying turbulence (Baglietto and Ninokata, 2005).
- Porous media approach. Here, the Navier-Stokes equations are averaged over space. This can result in very large meshes compared to the above methods, and may be considered to be effectively equivalent to subchannel methods but with more flexibility (Novak et al., 2018). Correlations for heat transfer and wall friction factors are required for accurate treatment.

Some codes that have been used for nuclear analysis include: OpenFOAM (Jasak et al., 2007), Nek5000 (NEK5000, 2019), ANSYS CFM, ANSYS FLUENT, STAR-CCM+, and Pronghorn (Novak et al., 2018).

Mechanical, thermo-mechanical, structural, and chemical analysis computational methods

For most analysis, the neutronics/thermal hydraulics is sufficient. However, it is also sometimes necessary to assess the fuel performance over cycle. The large temperature gradients present in nuclear fuel, as well as radiation damage and creation of fission products, greatly affects the microstructure of the fuel, which in turn affects the macroscopic thermal and mechanical properties.

Due to the large range of scales (microstructure vs. macroscopic structural), several modules are usually used. A mesoscale code such as MARMOT (Tonks et al., 2015) can predict microstructure evolution and determine the impact of fuel properties at a local scale. Next, an engineering-scale code such as BISON (Williamson et al., 2012) can predict the fuel stress and performance based on these properties.

Large-scale structural considerations can also be important for operations. Bowing and thermal expansion of fuel elements is especially important for fast reactor systems. These could be solved using a structural finite-element code such as ANSYS Mechanical (Bhashyam, 2002).

Finally, there has been an interest in modeling the chemistry of the fluid, especially as it relates to the formation of crud on the fuel rods. This importantly leads to crud-induced power shift (CIPS), and crud-induced localized corrosion. As a part of the CASL program, the MAMBA code has been developed to model this phenomenon (Short et al., 2013).

Core simulator frameworks

With all of the methods above, and the necessity to consistently couple them and repeatedly define complex problems, there is a need for core simulators or packages to bring these modules together under one framework. Many of these give a platform to use both low and high-fidelity methods where appropriate and to help verify accuracy. Although there are many ad hoc coupling programs that have been developed, some of the more advanced frameworks include:

- Simulation-based High-fidelity Advanced Reactor Prototyping (SHARP), a tool-kit for fast reactor analysis developed by Argonne National Laboratory (Mahadevan et al., 2014).
- Virtual Environment for Reactor Applications (VERA) and VERA-Core Simulator (VERA-CS), developed by the CASL program for light water reactor applications (Godfrey et al., 2017; Turner et al., 2016).
- Reactor Physics Workbench, developed in the United Kingdom for LWRs and Gas-cooled reactors (Hutt et al., 1991).
- The European NURESIM framework, designed to be a reference platform for reactor applications with legacy and modern tools (Chauliac et al., 2011).

Computational validation

At all stages of the computational simulation process to get a practical solution, there are approximations introduced. In order for users and regulators to have confidence in the nuclear simulations, verification and validation of these code results is required. Ideally, this comparison would be with a physical experiment, but this is not always possible or practical. In many cases, a code-to-code validation can be performed to get confidence that the approximations made in the low-order models are valid (Oberkampf and Roy, 2010).

Code-to-code validation involves the comparison of a low-order model that one wants to use for routine calculations to a high-order model that incorporates more realistic physics. A common example of this is comparison of nodal diffusion to Monte Carlo for neutronics (Leppänen et al., 2014). This would validate the spatial, angular, and energy discretization involved with the diffusion approximation. It is important to validate not only integral results, such as reactivity, but local quantities such as 2D and 3D pin (that is, fuel rod)-power.

The main limitation of code-to-code validation is that the codes may not adequately describe reality in several ways:

- Fundamental data they are given (such as cross-sections, which have significant uncertainty).
- Geometry and material information given, which may have uncertainties or be missing details or impurities, for example.
- Certain physics are not incorporated (e.g., thermal expansion or fuel bowing affecting neutronics).

However, code-to-code validation has a few advantages, such as being massively less costly than experiments, with the ability to test many configurations easily. It also allows the comparison of many local variables that may be challenging or impossible to measure, such as detailed, 3D power distributions.

Experimental validation

The gold-standard would be in validation against a full-scale reactor experiment. However, that is rarely possible, especially for new designs. The most important validation is for the thermal-hydraulics models, since they rely so heavily on experimental correlations. These can generally be broken down into separate effects tests, which try to focus on a single phenomenon, and integral effects tests, which incorporate many phenomena. Examples of such facilities include:

- Penn State University Rod Bundle Heat Transfer (RBHT) Test Facility (Hochreiter et al., 2010).
- Oregon State University Advanced Plant Experiment (APEX) (Reyes and Hochreiter, 1998), Multi-Application Small Light Water Reactor (MASLWR) (Reyes et al., 2007).
- Purdue University Multi-dimensional integral test Assembly (PUMA).
- University of California, Berkeley compact integral effects test (CIET) facility (Zweibaum et al., 2016).
- Nuclear Power Engineering Corporation PWR Sub-channel and Bundle Tests (PSBT) (Rubin et al., 2012).

For neutronics evaluations, there have been a number of high quality benchmark experiments done. Most of these have been incorporated into the International Reactor Physics Benchmark Experiment Evaluation Project (IRPhEP) and International Criticality Safety Benchmark Evaluation Project (ICSBEP) databases (Briggs et al., 2014).

The ultimate test of simulated predictions is real-world operational data from an operating reactor. This can be difficult to obtain for academic research, because plants typically do not share this proprietary information. Nuclear reactor vendors, on the other hand, do have access to this data in order to validate their proprietary thermal hydraulic, nuclear, and thermal-mechanical methods. Licensing and validation of these codes is required by regulatory agencies, including validation with plant operational data. However, since the reactor vendor goal is primarily to generate electricity safely and the operational environment is challenging, instrumentation may be more limited and operational conditions not as well-defined as in a designed experiment. One recent example of such operational data is from the Watts Bar Units 1 and 2, which are the most recently constructed reactors in the United States, and provided significant amount of data as part of the CASL program (Godfrey et al., 2016, 2017).

Core monitoring methods

Predicting reactor conditions must also be combined with measurements during operation. This provides another source of validation for the modeling tools and ensures that the reactor is always operating within the approved limiting conditions that were used for the safety analysis. The General Design Criteria in US CFR 50 Appendix A, mandates the monitoring of system variables and automated responses (GDC-13, GDC-20) to ensure that limits are not exceeded (U.S. Nuclear Regulatory Commission, 2007). Furthermore, higher accuracy models and on-line core monitoring can allow for smaller margins for operating reactors, leading to more advantageous power distributions in the core, which can result in better profitability due to the increased allowable power output.

Inlet and assembly outlet temperatures are generally measured with thermocouples, while the measurement of power distribution is more complex (Upadhyaya and Wood, 2021). During operation, the power is usually measured by a set of fixed self-powered neutron flux detectors throughout the core. Since the detector response may change throughout the core burnup (e.g., due to

changes in the number of neutrons released per fission with more plutonium), these detectors are periodically calibrated using movable neutron or gamma detectors. The overall heat balance of the plant can be used for an absolute calibration to the reactor power. Ex-core detectors (external to the core) can also be used, especially when operating at very low power levels, such as during startup, when the in-core power range detectors may not provide enough sensitivity. Ex-core detectors operate in a much more forgiving physical environment and with fewer spatial constraints, but also provide much less spatial resolution than in-core instrumentation.

Data collected from the detectors is used for automated protection systems, and is also evaluated with core simulator results for monitoring the fuel thermal limits. These comparisons can ensure that technical specifications limits were followed, such as departure from nucleate boiling, and Specified Acceptable Fuel Design Limits, such as local power peaking limits, are met.

Glossary

Actinides Any of the series of 15 metallic elements from actinium (atomic number 89) to lawrencium (atomic number 103) in the periodic table. They are all radioactive, the heavier members being extremely unstable and not of natural occurrence.

Analytical model A mathematical description of physical process or structure, system or component.

Anticipated operational occurrence Those conditions of normal operation which are expected to occur one or more times during the life of the nuclear power unit and include, but are not limited to, a loss of all off-site power, an inadvertent control rod withdrawal and tripping (shutting off) of the turbine generator set.

Anticipated transient without scram Events initiated as anticipated operational occurrences compounded by a failure in the normal reactor scram (i.e., immediate insertion of all safety rods) system.

Critical safety function Those safety functions that are essential to prevent a direct and immediate threat to the health and safety of the public. For conventional light water reactors, these are the accomplishing or maintaining of:(1)Reactivity control;(2)Reactor core cooling;(3)Reactor coolant system integrity (as a fission product barrier);(4)Primary reactor containment integrity; and(5)Radioactive effluent control.

Critical heat flux The condition in boiling heat transfer where the steam produced forms an insulating layer over the heated surface, leading to a reduction cooling at the heater surface. Surface temperature subsequently increase until a stable vapor film forms. This term is commonly associated with departure from nucleate boiling (DNB), which identifies the onset of the boiling regime transition from nucleate to film boiling.

Critical power The assembly power at which critical heat flux occurs. It is an empirical quantify used in Boiling Water Reactor safety analysis that must also consider the fluid quality of the coolant.

Design-basis event A design-basis event is a condition of normal operation, including anticipated operational occurrences, accidents (or transients), external events or natural phenomena for which the plant must be designed to ensure the three basic safety-related functions are achieved. Refer to the definition for “safety-related.”

Effective dose The tissue-weighted sum of the equivalent doses in all specified tissues and organs of the human body and represents the stochastic health risk to the whole body, which is the probability of cancer induction and genetic effects, of ionizing radiation. It takes into account the type of radiation and the nature of each organ or tissue being irradiated, and enables summation of organ doses due to varying levels and types of radiation, both internal and external, to produce an overall calculated effective dose. $E = \sum_R W_T \cdot H_T$, where E is the effective dose to the entire organism, H_T is the equivalent dose in

Sievert (Sv) absorbed by tissue ($1 \text{ Sv} = 1 \text{ joule/kg}$ —the equivalent biological effect of the deposit of a joule of radiation energy in a kilogram of human tissue), W_T is the tissue weighting factor defined by regulation.

Emergency core cooling system The emergency core cooling system is a system (or group of systems) required for LWRs that is designed to provide reactor core cooling following postulated accidents up to and including the design-basis loss-of-coolant accident. Its performance is analytically demonstrated and must conform to the acceptance criteria set forth in 10CFR50.46¹ regarding peak fuel cladding temperature, fuel cladding oxidation, hydrogen production, the maintenance of a coolable core geometry and successful core cooling in the long-term.

Engineered safety features Engineered safety features (ESF) are structures, systems, or components (SSCs) included in the plant design for the specific purpose of transient and accident prevention and mitigation. These SSCs may be dual purpose; that is, they may also serve non-accident mitigation functions. An example of a dual-purpose system is the decay heat removal system, which also typically provides low-pressure safety injection flow for a large loss-of-coolant accident. Typically, these SSCs are classified as safety-related, but certain ESFs (e.g., the BWR standby liquid control system) are not classified as safety-related because they exceed the requirements of the single-failure criterion and instead provide diversity and defense-in-depth for accident mitigation.

Figures-of-Merit Figures-of-merit are those quantitative standards of acceptance that are used to define acceptable answers for a safety analysis.

Fission products The nuclei (fission fragments) formed by the fission of heavy elements, plus the nuclide formed by the fission fragments' radioactive decay.

Limiting conditions for operation The lowest functional capability or performance levels of equipment required for continued operation of the facility without undue risk to the health and safety of the public.

Loss-of-coolant accident Those postulated accidents that result in a loss of reactor coolant at a rate in excess of the capability of the reactor makeup system from breaks in the reactor coolant pressure boundary, up to and including a break equivalent in size to the double-ended rupture of the largest pipe of the reactor coolant system.

Margin (i.e., design or safety) A quantitative relationship between a design evaluation result for a given event and a limit associated with a functional requirement.

Neutron activation the process in which neutron radiation induces radioactivity in materials, and occurs when atomic nuclei capture free neutrons, becoming heavier and entering excited states.

Postulated accidents Those design-basis occurrences not expected to occur during the life of the nuclear power plant, such as a loss-of-coolant accident.

Reactivity A term expressing the departure of a reactor system from criticality. A positive reactivity addition indicates a move toward supercriticality (power increase). A negative reactivity addition indicates a move toward subcriticality (power decrease).

Reactivity initiated (insertion) events (accidents) Events (or accidents) that involve positive reactivity insertion in the reactor core, thereby causing a power excursion and corresponding temperature increase, locally or globally.

Safety analysis An analysis that simulates the integrated response of the plant to a design-basis event (DBE) in order to confirm that functions of structures, systems and components are accomplished within their design basis and the nuclear safety criteria and safety analyses acceptance requirements are satisfied for the DBE.

Simulation A mathematical imitation of the response of a physical process or structure, system or component, represented by a model, to a state perturbation.

Introduction

National nuclear safety authorities, such as the Nuclear Regulatory Commission in the United States (USNRC) and the Autorité de Sûreté Nucléaire (ASN) in France, require that nuclear power plant designs be evaluated through physical testing and analysis. Because of the practical limits of physical testing, analysis is used as a surrogate to examine a broader range of equipment performance and possible failures or malfunctions. Of particular interest to nuclear regulators are failure sequences presenting the greatest physical challenge to the protective barriers separating radiological hazards, i.e., chemical elements derived from the splitting of the atom or fission products, from nuclear power plant staff and the public. The transient behavior resulting from such equipment failures or malfunctions are referred to as design-basis events. Using testing and analysis, nuclear power plant designers demonstrate that the resulting transient nature of the nuclear power plant's physical states, such as temperature, pressure, inventory, chemistry, or neutron balance, do not lead to a failure of the protective barriers. The use of transient analyses informs the nuclear power plant licensing process by validating its design envelope as defined by the limiting conditions of operation, limiting safety system settings, and technical (design) specifications.

¹The AEC was the predecessor of the USNRC, serving as both the promoter and regulator of nuclear energy project from 1946 until 1975.

Using analysis to confirm the design and safety adequacy of a nuclear power plant relies on strict adherence to an auditable calculational process, referred to as the evaluation model. An “evaluation model” is the collection of evidences related to a particular analysis. It will include one or more computer programs and all other information necessary to characterize a particular transient or accident scenario. This will include an analytical model provided by a mathematical description of the laws of (fluid) motion, physical phenomena and processes, plant design details and transient characteristics. In addition, the uncertainties, assumptions and limitations of the computer code(s) are also described and used to inform procedures for treating the program input and output information. Computer codes are to be qualified against the expected system behavior as observed from applicable experimental programs. Similarly, the way the computer codes are applied in the conduct of the evaluation model analysis is also subject to verification and validation.

This Transient Analysis Methods chapter summarizes the preparation of evaluation models from high-level requirements to the performance of nuclear-quality simulation and the interpretation of results for design and safety applications.

Regulatory requirements and guidance for nuclear safety analysis

Regulatory agencies like the USNRC and ASN are established and tasked with protecting public health and safety related to nuclear energy. Before a nuclear power plant can be built and operated, regulatory agencies require that the engineering organization advancing the project to submit a safety analysis report (SAR). The SAR describes the scope of the nuclear project in broad detail with an emphasis on analyses of transients and accidents that demonstrate design robustness. It identifies the anticipated hazards and the requirements for containing and managing these hazards. Results from physical testing and transient analysis appear in the SAR as evidence demonstrating that the role of physical barriers and other safeguards to protect and/or mitigate the release of fission products is maintained for all credible scenarios involving equipment failures or malfunctions.

The government regulations and guidance related to the content of a SAR begins with policies and standards for protections against ionizing radiation. These statements set regulatory objectives that build upon the principle that nuclear power plants provide adequate margins of safety and utilize effective means to accomplish their safety and security functions. Woven through the regulatory framework is the Defense-in-Depth requirement that nuclear power plants include the following: (a) design features for safe and reliable plant performance under normal operating conditions, (b) a plant protection system to protect the reactor against the consequences of any off-normal event, and (c) engineered safety features to provide additional safety margins for extremely unlikely and unforeseen events. Corresponding to this Defense-in-Depth philosophy, the full scope of physical testing and safety analysis that appears in a SAR examines the following:

- Prevention of abnormal operation and failures;
- Control of abnormal operation and detection of failures;
- Control of accidents within the design basis;
- Control of severe plant conditions;
- Individual effective dose from radiation to workers and public;
- Mitigation of radiological consequences;
- Integrity of physical barriers to the release of radioactive materials (i.e., fuel, fuel cladding, reactor coolant system and containment);
- Sustained capability of operators and safety systems; and
- Practical exclusion of large early releases of radioactive material.

For the breadth of physical testing and analysis required in the preparation of a SAR, the principal safety criteria relate to the effective dose from radiation. Dose estimates factor into how nuclear power plant staff performs periodic maintenance, how they respond during abnormal events, and where a nuclear power plant can be sited. Regarding the latter, plant siting explicitly considers the reactor design, the population density near the site and the site’s physical characteristics. It includes the acceptance criteria, in terms of the radiation dose, that are ultimately quantified from interpretations of transient and accident analysis. [Bley \(2021\)](#) details the safety and licensing requirements and acceptance criteria as they relate to radiological measures.

As [Bajorek \(2019\)](#) explains, transient analysis methods address how calculations are prepared, which, of course, incorporates regulations, but also includes the procedures and technical bases that provide evidence that the analyses are meaningful. Surrogate measures are emphasized that relate to the performance of one of the Defense-in-Depth measures, such as the integrity of the physical fission product barriers (e.g., fuel, fuel cladding, and reactor coolant pressure boundary) or the performance of an engineered safety feature. These measures, such as fuel bundle critical power in boiling water reactors (BWRs), critical heat flux in pressurized water reactors (PWRs), and peak clad temperature in all light water reactors (LWRs), are then compared against acceptance criteria. Events assumed to have radiological consequences are emphasized in safety assessments.

The particular set of measures and applicable acceptance criteria evaluated in transient and accident analysis begins with the assumed initial plant state and the nature of the equipment failures or malfunctions. Extensive failures are not considered credible for purposes of assessing the plant’s resilience to design-basis events. The regulatory intent for the set of events analyzed is that they represent a sufficiently broad number of situations to demonstrate a thorough assessment of credible risk-significant events. The basis of credibility for a particular event is determined from an assessment of risks, drawn from knowledge of the expected frequency of the associated set of failures (or malfunctions) and consequences from these failures.

Two general event classifications are recognized by national nuclear safety authorities, distinguished based on frequency:

- (1) Anticipated operational occurrences (AOOs)—Events expected to occur on a frequency of one or more times during the lifetime of the plant;
- (2) Postulated accidents (PAs)—Events not expected to occur that are evaluated to demonstrate design robustness.

Categorization of initiating events by either AOOs or PAs provides a foundational characteristic between events that serves to distinguish the more credible events from severe accidents. In 1973 the American Nuclear Society (ANS) published a standard (ANS 18.2 1973) entitled, "Nuclear Safety Criteria for the Design of Stationary Pressurized Water Reactor Plants." For safety analysts, this Standard organized events by their "condition." This "condition" primarily refers to event frequency and the classifications defined in that Standard are:

- Condition I: Events expected to occur frequently in the course of power operation, refueling, maintenance or plant maneuvering.
- Condition II: Events expected to occur on a frequency of once per year during plant operation.
- Condition III: Events expected to occur once in the lifetime of the plant.
- Condition IV: Events not expected to occur that are evaluated to demonstrate the adequacy of the design.
- Condition V: Hypothetical core damage events of very low frequency but with high radiological consequence, exceeding siting limits.

Tolerance for consequences from failure vary inversely with Condition. For Condition I and II events, for instance, there is zero tolerance for radiological releases. For Condition V events, radiological consequences are possible but, through design measures, the likelihood of these events is so low as to be practically eliminated. Because events in the Condition III and IV categories cannot be practically eliminated and have radiological consequences, they have received considerable regulatory attention. Events in these categories include anticipated transients without scram (ATWS) and loss-of-coolant accidents (LOCA).

An ATWS is an AOO followed by a failure of the reactor control and protection system to shut down the reactor via an automatic scram or reactor trip. Failure of the reactor protection system to provide a scram when required could cause an otherwise minor event to turn into a high consequence accident. Because of the potential consequence of ATWS, regulations have evolved to require diverse, independent, reactor trip functionality. Rules pertaining to ATWS are generally met by either demonstrating that the reactor protection system meets the diversity requirements or by providing a separate hardware backup scram system. The protection system must include a completely independent reactor scram function, including diversity in everything from sensors to final actuation of the scram.

A LOCA is an event characterized by a loss of reactor coolant at a rate in excess of the capability of the reactor coolant makeup system to mitigate. This is expected from breaks in the reactor coolant pressure boundary, up to and including a break equivalent in size to the double-ended rupture of the largest pipe of the reactor coolant system. The larger sized LOCAs can be severe, and for this reason, it is frequently referred to as the Maximum Hypothetical Accident. Given this potential, the complexity of the phenomena associated with the event and the performance of a plant's safety features designed to restore cooling the reactor core, analysis of the LOCA has received special attention in nuclear power plant regulations. Notably, these regulations are specific with regard to reactor and fuel design, LWRs with zirconium-clad fuel elements.

Since the 1970s, LOCA-related regulations worldwide include a specific procedure for simulating the performance of a nuclear power plant's emergency core cooling system (ECCS) deterministically. In the United States, this procedure is referred to as "Appendix K," a reference to its location in the U.S. Code of Federal Regulations on nuclear energy (i.e., 10 CFR 50 Appendix K). The features of this model that incorporate penalizing assumptions to ensure estimates for peak fuel cladding temperature and other acceptance criteria by this method are conservative.

Beginning in 1988 in the United States, followed by several other countries with nuclear power plants, rules allowing the use of best-estimate computer codes with some relaxation on the conservatism described above emerged. The degree to which best-estimate solutions to the LOCA analysis are permitted vary considerably among these countries. Evaluation methodologies described as best-estimate plus uncertainty (BEPU) methods have emerged as the preferred approach and most aligned with principles of best-estimate analysis that rely on the complementary application of science- and data-based analytics.

Design-basis event characterization

Given the predominance of LWR technology in the commercial nuclear industry, the characterization of design-basis events has been largely vetted through decades of deliberation between regulatory agencies and the industry. Consequently, regulations for the commercial nuclear power industry in most countries, with Canada and the UK notably exceptions, incorporate LWR-specific prescription for the particular set of design-basis events (DBE) that must be analyzed. To support the emergence of LWR and non-LWR advanced reactors, the responsibility for DBE characterization is with the design and engineering organization. To do so, engineers apply hazards analyses.

A successful hazards analysis requires the analyst to include all risk-significant failure modes for each contributing element in the plant. A DBE derives its detail beginning at the plant scale then through an assessment of progressively shrinking scales: facility, system, subsystem, component, and part. Methods vary with the degree to which probabilistic characteristics are considered. Not surprisingly, the original assessments in this regard, prepared by the Atomic Energy Commission² (AEC) in the United States

²Presented in generalized units of T = Time, L = Length, Θ = Temperature, M = Mass, E = Energy.

in 1950s and 1960s, had relatively little data from which to draw probabilistic insights. Rather, the AEC incorporated experience from their sponsorship of test programs and high-level consideration of risk. This experience provided the basis for identifying system-level failures corresponding to one or more critical safety functions (Martin, 2019).

System-level failure modes are failures reflecting operability deviations challenging system-level structures, systems or components that are relied upon to remain functional during and following DBEs. Risk insights are considered to the extent to which DBEs can be categorized into the Conditions previously defined. The severity of the event is then compounded by the requirement that the challenged critical safety function, as served by one or more engineered safety features, is degraded by a “worst single failure.”

The importance of the single-failure criterion cannot be overstated. This deterministic criterion specifies an approach to obtaining optimal redundancy of a system or of a group of components ensuring a high degree of reliability. It requires a systematic search of potential single failures followed by an evaluation of the effect of each single failure on the ability of the plant’s engineered safety features to satisfy the specified principal design criteria, each of which relate to the protection of one or more critical safety functions or fission product barriers.

A single-failure analysis methodology incorporates both qualitative and quantitative evaluation measures, yielding candidate limiting equipment failures and malfunctions for further characterization and, ultimately, to serve as the basis for a plant’s design-basis envelope. The assessment does not require consideration of any conceivable failure that could occur; rather, “only those systems or components judged to have a credible chance of failure are assumed to fail in applying the single-failure criterion” (Institute of Electrical and Electronics Engineers, 2001). The common activities performed in the assessment of the worst single-failure include:

- Identifying structures, systems and components important to safety;
- Listing the credible vulnerabilities with respect to each critical safety function;
- Defining figure(s)-of-merit and criteria that assure the critical safety function;
- Evaluating the impact of failure for each vulnerability in terms of its influence on the figure(s)-of-merit and design and acceptance criteria.

Other DBE attributes are evaluated deterministically, incorporating a nuclear power plant’s limiting conditions of operation and technical specifications targets. In the characterization of DBEs, these targets are commonly implemented as initial conditions in a transient or accident analysis. The deterministic approach to characterizing the initial condition is to identify the plant state (i.e., in terms of model parameters in an analysis) that will lead to the smallest calculated margins in the figures-of-merit relative to acceptance criteria. Many of these will be set consistent with the plant’s Technical Specifications. For example, core power is set at nominal full power plus instrument uncertainty, core decay heat is set assuming infinite operating time, core outlet temperature is set at the maximum allowable, and core flow rate is set at a minimum.

Design-basis characterization methods that were originally applied to the commercial nuclear industry were technology neutral. Given that the industry favored LWR technology (with government encouragement), the efforts by national regulators to identify and characterize DBEs has been documented only in terms of how they have been applied for LWRs. In the United States, the most complete description of LWR DBEs is documented in NUREG-0800, Standard Review Plan (U.S. Nuclear Regulatory Commission, 2007). The many identified events can be generalized for a broader spectrum of nuclear power plant designs as:

- Increase in heat removal by a cooling system
- Decrease in heat removal by a cooling system
- Flow rate transients (such as hydrodynamic flow instability events)
- Decrease in coolant system inventory
- Increase in coolant system inventory
- Reactivity transients

where the reference to “coolant systems” can refer to systems dedicated to the core, primary coolant, containment or one of several auxiliary coolant systems.

Since the AEC’s original determination of LWR DBEs, reliability analysis has matured into analytically-consistent methodologies, such as functional hazard assessment, failure modes and effects analysis, and event and fault tree analysis (Lee and McCormick, 2011). More recent methods, such as Aldemir (2013) and Idaho National Laboratory (2017), extend the reliance on risk insights to a broader selection of event characteristics. Regardless of the preferred method, the objective of the hazards analysis is to systematically assess postulated failures and determine the plant’s response.

Evaluation model, phenomenological importance and scaling

The development of the knowledge bases supporting transient and accident analysis relies upon both “top-down” and “bottom-up” elements. The “top-down” element relates to the applicability of governing equations, constitutive relationships or models (i.e., models describing phenomenological behavior) and their organization as an analytical solution. The “bottom-up” element relates to the completeness, consistency and overall performance of the evaluation model.

Given the complexity of nuclear power plant transient analysis, the analytical solution is provided by a computer code, often consisting of thousands of lines of coding. As the centerpiece of the evaluation model, every facet of the computer code is

characterized and described. Since the computer code is expected to emulate a real system, the analytical solution must be shown to apply to the transient scenarios that the analyst expects to resolve through simulation. As such, the more important mass, momentum, and energy transport mechanisms, i.e., the phenomena and processes, are explicitly represented in the analytical model. Once the governing equations and constitutive models describing these transport mechanisms are organized into a computer code, the code's performance is reviewed and assessed in terms of numerical convergence, stability, and property conservation and its fidelity against separate- or integral-effects test data. This review involves three distinct activities of verification, validation, and uncertainty quantification, which are described in later sections; but fundamental to these activities is the knowledge base of physical phenomena expected to be present during the DBEs of a real system. This knowledge base establishes the set of requirements for the evaluation model and the computer code that facilitates transient analysis.

Managing knowledge comprises the strategy used to translate the insights and experiences relating nuclear power system performance during DBEs to a complete and self-consistent evaluation methodology. In raw form, this knowledge exists in individuals and appears in documents that preserve our understanding of nuclear power plant DBEs. Given the breadth of this knowledge base, the development of an evaluation model begins by identifying a reduced set of more important phenomena and processes influencing the physical state of a nuclear power plant during a DBE. The Phenomena Identification and Ranking Table (PIRT) methodology is broadly applied in the nuclear industry for this purpose (Wilson and Boyack, 1998).

Fundamentally, computer codes for transient analysis of nuclear power systems must model the principal phenomena associated with the particular plant and scenario of interest. This specificity provides the initial prioritization of the knowledge base. The PIRT process provides a framework for the structured collection and documentation of subject matter expert judgment with respect to phenomena and their importance in an evaluation model. The particular transient event or accident is then broken into multiple phases characterized by the dominant phenomena and processes present and their effect on measurable loads (i.e., figures-of-merit) on the real system. The PIRT organizes the identified phenomena by each system and component involved in the transient and by ranking the importance of the phenomena relative to the figures-of-merit in each phase. In addition, the quality or state of the phenomena-specific knowledge base is also assessed and an overall risk assessment is made based on the combination of importance ranking and the state of knowledge. As such, it provides part of the basis for the following evaluation model development objectives:

- Determining the scope of the effort required to verify the computer code (i.e., does the computer code properly model the important phenomena).
- Identifying phenomenological parameters that can be quantified for evaluating and propagating uncertainties.
- Identifying or developing test data that contain the appropriate phenomena during each accident phase and support the quantification of evaluation model uncertainties.

The majority of the effort in developing an evaluation model is that associated with the last objective. With the important phenomena identified, test programs are identified or designed that provide data appropriate for measuring the performance of the computer code and adequacy of the evaluation model, generally.

Since events in nuclear power plants involve complex interactions between fluid and structure exchanging mass, momentum, and energy, the hierarchical nature of the phenomena and processes as modeled in a computer code must be aligned with that appearing in a real system. To address this requirement, a scaling analysis is performed. Scaling analysis is broadly practiced in all disciplines of engineering. For transient analysis of nuclear power plants, the Hierarchical Two-Tiered Scaling (H2TS) methodology is commonly applied (Zuber, 1991), which builds on and extends the Ishii and Jones (1976) method. The Dynamic System Scaling methodology (Reyes and Frepoli, 2019) presents a contemporary unifying approach to scaling by incorporating a geometric analogy.

Similar to the evaluation model itself, the two tiers of the H2TS methodology are the top-down or system approach and the bottom-up or process approach. The top-down approach yields a set of nondimensional scaling or similarity parameters that are expressed as characteristic time ratios. The second tier or bottom-up approach provides more detailed, localized analyses of the important processes. The two tiers provide an overall analysis methodology that is objective, tractable and technically justifiable.

In contrast to the PIRT process that relies on the observational subjectivity of experts, the H2TS emphasizes a physically-based hierarchy (i.e., of the form facility, system, subsystem, etc.). Since phenomena or processes can appear at any scale, a pattern emerges between the chronology of knowledge development and phenomena or process scale. Notably, statics and dynamics are fundamental to processes at all scales and appear associated with the system and subsystems, respectively. Modules are commonly equated with components; however, generically, they represent contributions of work or energy from one or more physical domains (e.g., hydraulics, heat transfer, fission, etc.). The actual fluid(s) or, more generically, the "medium of motion" are the constituents. Fluid state in terms of its appearance as a solid, liquid or gas relates to its phase. The configuration of phases is described by both the geometry encompassing the fluid(s) and the topological arrangement within that geometry. Fig. 1 illustrates a conceptual hierarchical knowledge base decomposition of a PWR DBE. At the process level appear a set of phenomena that would appear originally in a PIRT.

Expressions for the nondimensional similarity parameters are derived from an analytical model that relates the phenomenon or process at the scale of interest to figures-of-merit. Using test program design data and results from physical or computer-simulated testing, these parameters can be quantified and compared for alignment. Where test program data and computer simulations compare well, the quality of the two is considered adequate. In contrast, discrepancies suggest shortcomings in either the test or the computer code or, possibly, both, requiring further investigation or other analytical treatment to resolve.

Fig. 1 Hierarchical knowledge base decomposition example for a PWR DBE.

Analytical requirements and software

The objective of the evaluation model for transient analysis of a nuclear power plant is to establish or verify a measure of design adequacy under normal operation and DBEs. Given the complexity of these applications, analysis relies on a hybrid of physics- and evidence-based computer codes for simulation of nuclear power plant processes. The virtual environment of this software combines the knowledge of the plant geometry, boundary and initial conditions with knowledge of the important physical phenomena. Ensuring quality transient analysis begins with a strong foundation in thermal-hydraulic phenomenology, which is to be translated into requirements, model theory, software and applications.

For the commercial nuclear power industry based on LWR technology, the greatest challenge to this effort has been the modeling of two-phase fluid (i.e., liquid water and steam) behavior. An inaccurate solution could lead to an under prediction of important measures of safety like fuel and clad temperatures or the timing of when coolant starts to boil. As such, the development evolution of these computer codes has been driven by emphasizing such figures-of-merit. This has required coincident experimental program for data to characterize two-phase flow. Over the decades of related research, these pursuits have revealed that the related phenomena impacting nuclear safety measures are many and varied.

The method of modeling in these computer codes involves a set of governing or field equations used to model the two-phase fluid flow. “Governing equations” refer to equations for the conservation of mass, energy and momentum of the working fluid and, optionally, a non-condensable gas and/or a liquid solute. These equations are solved to provide predictions of the spatial distribution of liquid, steam and non-condensable mass as well as the velocity and energy state for each phase. These governing equations contain parametric dependencies related to geometry, phenomena and processes modeled by these equations. Solution is only possible with a complete and consistent set of models and correlations providing the necessary mathematical closure.

Since the mid-1970s, the six-equation, Two-Fluid Model is the predominant description for two-phase flow in thermal-hydraulic systems codes for nuclear safety analysis (Ishii, 1975). The distinguishing characteristic of the Two-Fluid model is that it considers mass, momentum, and energy transport between the liquid and vapor phases. In the more common solutions to the Two-Fluid model, appearing below, the dependent variables are vapor void fraction (α_v), pressure (P), liquid-phase total energy or enthalpy (h_l), and vapor-phase enthalpy (h_v), liquid velocity (v_l) and vapor velocity (v_v). From Martin et al. (2019a), the phasic mass continuity equations are

$$\overbrace{\frac{\partial}{\partial t}(\alpha_k \rho_k)}^{\text{time rate of change}} + \overbrace{\frac{\partial}{\partial z}(\alpha_k \rho_k v_{kz})}^{\text{advection}} = \overbrace{\Gamma_k}^{\text{source/sink}}, \quad (1)$$

where ρ_k are liquid and vapor density (i.e., ρ_l and ρ_v), respectively, α_k is liquid and vapor void fraction (i.e., α_l and α_v), respectively and v_{kz} is the phasic velocity in the z -direction (v_{lz} and v_{vz}), respectively. For the mass continuity equation, the only source or sink for the liquid and vapor phases of water is interfacial mass transfer (Γ); namely, boiling, flashing, evaporation (in the presence of non-condensables) and condensation. In order to conserve mass, the relationship between the phasic terms at the interface (also known as the jump conditions) can be written as

$$-\Gamma_l = \Gamma_v = \Gamma, \quad (2)$$

which states that a given mass of liquid gained is balanced by the loss of an equivalent amount of vapor.

The phasic momentum equations are

$$\begin{aligned} & \overbrace{V(\alpha\rho)_k \frac{\partial}{\partial t}(v_{kz})}^{\text{time rate of change}} + \overbrace{V(\alpha\rho v_z)_k \frac{\partial}{\partial z}(v_{kz})}^{\text{advection}} = \\ & \overbrace{-\Delta z \frac{\partial}{\partial z}(p\alpha_k A_z)}^{\text{Pressure Gradient}} - \overbrace{\alpha_k \rho_k V g \sin\theta}^{\text{gravity body force}} - \overbrace{\tau_{kw} P_{kw} \Delta z}^{\text{wall shear}} \\ & - \overbrace{\tau_{ki} A_i}^{\text{interfacial shear}} + \overbrace{(v_{ki} - v_{kz}) \Gamma_k V}^{\text{momentum transfer by mass transfer}} \end{aligned} \quad (3)$$

where z , P_w , A_z , A_i , and V are, respectively, the control volume length, perimeter, cross-sectional area, phasic interfacial area, and volume; g is the gravitational constant; τ_{kw} and τ_{ki} are the wall and interfacial shear stress terms; and other variables and subscripts as defined with Eqs. (1) and (2). In this expression, the final two equation terms must sum to zero when the phasic equations are added together to form the mixture equation. In practice, the terms are typically treated individually instead of as a sum. Namely,

$$\tau_{li} A_i = -\tau_{vi} A_i \text{ and } v_{li} \Gamma_l V = -v_{vi} \Gamma_v V \quad (4)$$

The interfacial shear term (τ_{li}) is typically written as

$$\tau_{li} = f_i \frac{1}{2} \rho (v_v^2 - v_l^2), \quad (5)$$

where the interfacial friction factor (f_i) and the phasic density (ρ) to be used in the expression depend on the flow topology, describing the configuration of vapor and liquid together, such as a predominant liquid field with bubble or slugs of vapor, or a predominant vapor field with dispersed droplets. These are examples of flow regimes.

The energy equation is most often written in terms of internal energy or enthalpy. Both of these state conditions are directly related to temperature via the specific heat at constant volume and constant pressure, respectively. A common form of the energy equation is given as

$$\begin{aligned} & \overbrace{V \frac{\partial}{\partial t} [(\alpha\rho h^0)_k]}^{\text{time rate of change}} + \overbrace{\frac{\partial}{\partial z} [(\alpha\rho v_z h^0)_k V]}^{\text{advection}} = \\ & - \overbrace{(\alpha\rho v_z)_k V g \sin\theta}^{\text{gravity}} - \overbrace{pV \frac{\partial \alpha_k}{\partial t}}^{\text{pressure work}} + \overbrace{q_k''' V}^{\text{generation}} + \overbrace{q_{wk}'' A_w}^{\text{wall heat transfer}}, \\ & + \overbrace{q_{ik}'' A_i}^{\text{interfacial heat transfer}} + \overbrace{\Gamma_k h_{ki}^0 V}^{\text{energy with mass transfer}} \end{aligned} \quad (6)$$

In this equation, h_k^0 is the phasic enthalpy and h_{ki}^0 is the phasic enthalpy associated with mass transfer. q_k''' , q_{wk}'' , and q_{ik}'' are the internal (volumetric) heat generation, wall heat flux and interfacial heat flux, respectively. For a system in thermal equilibrium, this would represent a saturated phasic enthalpy. However, in the case of thermal non-equilibrium the use of purely saturated enthalpies for the interfacial terms can lead to non-physical results. To avoid this problem, the calculation of the effective enthalpy is chosen based on the direction of mass transfer. Namely, the disappearing phase uses the local phasic enthalpy and the appearing phase uses the saturated value. In other words, the disappearing phase takes all of its energy with it, while the appearing phase is born at the saturated value.

Significant thermal non-equilibrium is common during a LOCA. As such, thermal-hydraulic system codes must be able to predict thermal non-equilibrium between the fluid phases. Specifically, the codes must be able to predict stable ($T_l < T_{sat}$ and $T_v > T_{sat}$) and meta-stable conditions ($T_l > T_{sat}$ and $T_v < T_{sat}$). Interfacial heat transfer (denoted as the product $q_{ik}'' A_i$) is included in the phasic energy equations. This energy is commonly described as the transfer of energy from the fluid at its phasic temperature to a massless interface that exists at a saturation temperature. The interfacial heat flux (q_{ik}'') is defined using an analog of Newton's Law of Cooling.

$$q''_{ik} = h_{ik}(T_{\text{sat}} - T_k), \quad (7)$$

In order to conserve energy, the sum of the last two terms in the energy equation must be equal to 0.0 when summed over the liquid and vapor phases.

$$\Gamma_l h_{li}^0 V + q''_{il} A_i = \Gamma_v h_{vi}^0 V + q''_{iv} A_i, \quad (8)$$

Rearranging the equation and remembering the relationship between the liquid and vapor side interfacial mass transfer terms allows us to develop an equation for the interfacial mass transfer, as a function of the interfacial heat transfer rates and the effective enthalpies.

$$\Gamma = -\frac{(q''_{iv} + q''_{il})A_i}{(h_{vi}^0 - h_{li}^0)V}, \quad (9)$$

The previously described set of governing equations actually contains more variables than equations. Model closure is the task of resolving those variables that are outside of the equation set. Among these variables in the described two-fluid model are contributions from large-scale processes like work on the fluid from a pump or energy from a nuclear reactor. It also includes smaller-scale phenomena like wall friction and fluid properties. The principal complexity of a two-phase hydrodynamic model closure resides in the derivation and solution of the constitutive relationships addressing interfacial phenomena. These are commonly resolved by applying (empirically derived) flow-regime-dependent models for interphase friction (drag) and mass and heat transfer. Additional constitutive relations include solutions for the coefficient of virtual mass, wall friction, wall heat transfer and direct (sensible) heat transfer.

Model closure for simulating nuclear reactor transients must include the power response from changes in core reactivity. For most transient analyses, the point kinetics model is considered conservative and thus adequate for safety assessments. The point kinetics model is the simplest model that can be used to compute power behavior in a nuclear reactor. Power is computed using the space-independent or point kinetic approximation that assumes that power can be separated into space and time functions. Eqs. (1)–(5) describe the point kinetics model (Tsvetkov, 2021) used in most thermal-hydraulic system codes, including RELAP5-3D.

$$\frac{dn(t)}{dt} = \frac{\beta_{\text{eff}}}{\Lambda} [\rho_s(t) - 1]n(t) + \sum_{i=1}^N \lambda_i C_i(t) + S \quad (10)$$

$$\frac{dC_i(t)}{dt} = \frac{\beta_i}{\Lambda} n(t) - \lambda_i C_i(t) \quad i = 1, 2, 3, \dots, N \quad (11)$$

$$\psi(t) = V \Sigma_f n(t) v \quad (12)$$

$$P_f(t) = Q_f \psi(t) \quad (13)$$

$$\rho_s(t) = \sum_i \rho_i(T, x) \quad (14)$$

where t , Time³ (T); n , neutron density (#/L³); C_i , concentration of delayed neutron precursors of group i (#/L³); β_i , delayed neutron fraction of group i ; β_{eff} , effective delayed neutron fraction; Λ , prompt neutron generation time (T); ρ_s , ρ_i , reactivity ((dk/k)/ β_{eff}); λ_i , decay constant of group i (1/T); S , neutron source (#/(L³·T)); v , neutron velocity (L/T); ψ , fission rate (#/T); Σ_f , fission cross section (1/L); P_f , immediate fission power (E/T); Q_f , immediate fission energy per fission (E); V , fuel volume (L³); N , number of delayed neutron precursor groups; T , temperature (Θ); x , spatial position (L³)

The fuel heat generation includes contributions from (1) fission power, (2) power from fission product decay, (3) power from actinide product decay, and (4) power from decay due to neutron capture in core constituents (i.e., neutron activation). Fission power is important only until a short period following reactor trip, vanishing as the reactor becomes subcritical. The remaining decay power terms are commonly calculated based on an ANSI/ANS decay heat standard. As such, total volumetric power ($Q_t'''(t)$) at time t is the summation of the fission power and delayed contributors ($P_i(t)$) divided by the core volume:

$$Q_t'''(t) = \frac{1}{V} \left(Q_f \psi(t) + \sum_{i=1}^N P_i(t) \right) \quad i = 1, 2, 3, \dots, N \quad (15)$$

The simple reactivity model given in Eqs. (10)–(15) is broadly applicable to the analysis of PWR AOOs. In BWR AOOs and accidents, the presence of coolant voids requires at least one dimensional spatial resolution and preferably three-dimensional.

Reactivity initiated accidents (RIA) are a class of design-basis events that require higher spatial fidelity for both PWRs and BWR. Neutron kinetics in RIAs is modeled using either a multi-dimensional diffusion or transport model (Avramova and Ivanov, 2019). At a minimum, the time-dependent neutron flux in these models depends on space and energy. To benefit from this high fidelity model, there must be a proper mapping between thermal-hydraulic control volumes and spatial kinetics nodes. Given the increased

³Title 10 of the U.S. Code of Federal Regulations (CFR), Part 50, Section 46.

modeling requirements, these multi-physics simulations can be computationally challenging. As such, they historically have only been utilized in those scenarios where pronounced 3-D asymmetric characteristics are expected; however, with advances in computing, 3-D multi-physics modeling is becoming more commonplace.

Verification and validation

Nuclear regulatory frameworks require that the sufficiency of transient analysis computer codes be demonstrated through either analysis, test programs and experience, or combination thereof. In addition, this sufficiency must be explained specific to individual phenomena and processes and for the collective or integral effects of these phenomena and processes. Of particular interest are the interdependent effects involving engineered safety features. In all settings, assessments involve experimental data spanning a sufficient range of normal conditions and transient conditions, in addition to accident sequences.

The utility of computational methods is invaluable to nuclear system designers and safety analysts. Given the strong societal interest in the reliability and robustness of these complex systems, the credibility of software prediction used in these applications must be extensively scrutinized. Verification and validation (V&V) are the primary methods for building and quantifying confidence in analytical capability.

Verification is the process of determining that the numerical algorithms are correctly implemented in the computer code and of identifying errors in the software. It involves the confirmation that documented statements accurately reflect the coding and evaluation methodology procedural mechanics. It typically takes the form of a line-by-line review of coding and supporting evaluation documentation, failure-modes-and-effects analysis, and confirmation of compliance with an accepted quality assurance plan. Standard problems, benchmarks with other codes, or analytical exercises with known solutions (e.g., *Method of Manufactured Solutions* (Salari and Knupp, 2000)) are also useful complements to explicit code-to-data comparisons.

Validation is the process of determining the degree to which a model is an accurate representation of the real world from the perspective of the intended uses of the model. Computational tools are validated using an appropriate developmental assessment matrix consisting of both separate and integral effects test program data that address the more important phenomena influencing the ultimate figure(s)-of-merit. The assessment matrix supports the evaluation model development in defining nodalization, quantifying code accuracy, and demonstrating any code or model scaling effects. The principal objectives are to demonstrate sufficient accuracy in modeling dominant physical processes, appropriate nodalization, independence of scale effects, and the relative insensitivity of compensating error.

V&V activities are derived from the same source of requirements used to develop the computer code: the PIRT and scaling analysis. Application of these methodologies provide the modeling and simulation requirements related to the more important physical phenomena and processes. As is the nature of complex systems, a thorough PIRT and scaling analysis contain multiple levels of organization defined by the phenomena and processes that appear and interact at a common scale. A V&V hierarchy is prepared to match equivalent tiers of model theory expressed in computer code predictions and experimental outcomes, such as that shown in Fig. 2 (Oberkampf and Roy, 2010).

This approach divides the complex engineering system of interest, i.e., the nuclear power plant, into progressively more fundamental tiers. The strategy in the tiered approach is to assess how accurately the computational model (i.e., governing equations and closure relations) and application results compare with independently sourced information such as theory manuals, journal articles, and data from test facilities. Individual V&V tests then proceed down and across the hierarchical model. Verification is demonstrated by the alignment of theory and its translation into lines of computer code. Validation is demonstrated by the alignment of simulation outcomes with experiment results. Ohkawa and Ratnayake (2019) provide an extensive summary of datasets compiled for the nuclear industry.

Fig. 2 Validation hierarchy tiers. From Figure 10.7 in Oberkampf WL and Roy CJ (2010) *Verification and Validation in Scientific Computing*. Cambridge, UK: Cambridge University Press.

Deterministic and best-estimate analysis methods

Per Martin et al. (2019b), transient and accident analyses are prepared to determine a nuclear power plant's physical state following equipment failure or malfunction. This involves a logical progression from requirements to inquiry to experimentation to modeling, simulation, and the interpretation of results. Ultimately, this exercise concludes with procedures for quantifying the effective dose from radiation from a hypothetical release of radioactive material. In between resides a mix of deterministic and probabilistic insights into plant design and its nuclear and thermal-hydraulic response to transients and accidents.

Objectivity is essential in an evaluation model. In early years of the nuclear industry, this objectivity was mandated through regulatory requirements explicitly specifying analytical procedures. This was necessary to address large gaps in the nuclear thermal-hydraulic knowledgebase at the time. As this knowledgebase was expanded through experimentation and theory, regulatory emphasis shifted toward uncertainty management. With perfect knowledge, precise evaluation of actual margins relating to the limits and set points would be possible. In practice, even with detailed knowledge of physical phenomena and processes, uncertainties remained. The benefit of this knowledge is that uncertainties are quantifiable and, thus, lend themselves to explicit treatment in evaluation models.

Analysis uncertainty in modeling and simulation has many sources. These include those associated with approximated models that describe the underlying physics; those associated with the settings of parameters used in physical models and correlations; those associated with performing a simulation at a given spatial resolution; and those associated with approximations in the numerical algorithms. Uncertainty quantification is the process of characterizing, estimating, propagating, and analyzing all kinds of uncertainty to support decision-making.

Fig. 3 graphically illustrates the difference in the convolution of uncertainty within deterministic and statistically (or probabilistically) based (i.e., BEPU) evaluation models. Within deterministic evaluation models, key parameters are conservatively bounded, effectively “stacked” upon other conservatisms in a single calculation. “Appendix K” evaluation models, as recognized in the United States, are deterministic. With statistically based evaluation models, key parameters are sampled over an uncertainty range, requiring several calculations.

Since the 1988 U.S. regulatory rule change allowing for statistically-based evaluation models for LOCAs (U.S. Nuclear Regulatory Commission, 2017), there has been notable industry investment in uncertainty quantification methods for thermal-hydraulic models in computer codes for nuclear power plant applications. These methods center upon the evaluation of parametric and system response uncertainties, where system response uncertainties are derived from the convolution of one or more parametric uncertainty models. In this context, uncertainty quantification begins with a model or correlation, data, and a clear qualitative statement that captures the assumptions associated with measured values. The latter element is key in that observations of phenomena will often inherit a bias associated with data acquisition methods. For example, core heat flux datum is a function of the movement of coolant, the fluid properties, the geometry of the core, fuel materials and configuration, the possible stochastic nature of the underlying phenomena, the location and density of instrumentation, calibration of the instrumentation, and post-test data reduction. As with the type of data, such assumptions are not equally important. What is important is that the application of uncertainty models is consistent with the original assumptions.

The outcome from PIRT and scaling analyses serve to identify a manageable set of uncertainty parameters. The quantification process requires that data from separate-effects tests be segregated into control and validation sets. The control set is used to derive the uncertainty and, as the name implies, the validation set is used to validate the integrity of the uncertainty model. A general

Fig. 3 Contrast between deterministic and statistical convolution of uncertainty.

uncertainty model is characterized by a bias and a probability density function; however, the uncertainty model does not necessarily reflect a task unique to performing a statistically-based analysis. A deterministic analysis can be viewed as one built from uncertainty models consisting of parameter biases. While the bias may simply reflect a static error in a model parameter, it can also be used to define a conservative or bounding treatment based on a limited set of test data.

With the principal elements of the evaluation model completed, meaningful analysis of nuclear power plant transients and accident is possible. Regardless of whether analysis is performed deterministically or using statistically-based methods, the preparation of analysis is similar:

- Gather pre-requisite code input data (e.g., design, fuel/core analysis or plant data)
- Identify code parameters important to analysis measures-of-interest
- Quantify uncertainty treatment for parameter set (e.g., biases and/or probability density)
- Develop base input for the computer codes (i.e., design information)
- For statistically-based (BEPU) evaluation models, build calculation suite from sampling the uncertainty domain
- Perform calculations
- Evaluate parametric sensitivity of figures-of-merit
- Formalize analysis guidance
- Perform analyses of record

Anticipated operational occurrences and postulated accidents

The scope of analyses performed for nuclear power plants is broad. These include (Ergün et al., 2019):

- Reactor coolant system—Characterizes the RCS pressure boundary, a physical fission product barrier and defines the design envelope for thermal-hydraulic conditions during normal operation and design-basis events.
- Fuel design and performance—Characterizes the configuration of fuel and the material, and structural requirements for the fuel rod cladding, a physical fission product barrier.
- Core design and performance—Characterizes the design envelope for fuel materials and reactor physics during normal operation and design-basis events.
- Instrumentation and controls (I&C)—Characterizes the protection and safeguards systems, defined by several monitored plant process inputs, translated as binary signals that result in the actuation of systems serving the critical safety functions of reactivity control, RCS pressure and inventory control, RCS heat removal, containment environment and isolation, containment integrity, and radiation and radioactive effluent control.
- Containment performance—Characterizes the design envelope for the containment, a physical fission product barrier.
- Structural and loss-of-coolant accident (LOCA) loads—Characterizes the design envelope of structural forces on the containment and critical load-bearing and safety equipment.
- Radiological, severe accidents and probabilistic risk assessment (PRA)—Characterizes the design envelope of the radiological source term and the risk and consequences related to the release and transport of radionuclides from the fuel into the environment.
- Auxiliary systems—Characterizes new and spent fuel handling and storage, water systems, process auxiliaries, air handling systems, fire protection and other systems that support the overall mission of plant operation.
- Technical specifications—Captures the design envelope requirements for SSCs supporting critical safety functions from other engineering disciplines to support administrative coordination and controls, including procurement.
- Accident management—Characterizes programs, plans, training, exercises and resources necessary to prepare personnel to operate, maintain and effectively react to off-normal situations, including those arising from terrorism or natural events. It includes emergency preparedness, whose objective is to ensure that nuclear power plant operators can implement measures to protect public health and safety in the event of a radiological emergency.

For LWRs, the DBEs are identified and characterized per methods described in Section “**Design-Basis Event Characterization.**” As noted in that section, analysis categories fall into the following general types: undercooling, overcooling, flow rate transients, an increase in coolant system inventory, a decrease in coolant system inventory, reactivity transients. In addition, consideration is given to what might occur if the reactor protection system fails to respond to these events as intended, generally by providing an automatic reactor scram. Such scenarios, referred to as anticipated transients without scram (ATWS), are analytically conservative and contribute to assuring a robust design.

In the following, several PWR- and BWR-specific DBEs are described under the categories of Anticipated Operational Occurrences and Postulated Accidents, drawn from Buschman and Meholic (2019), Todd (2019) and Avramova and Ivanov (2019).

Anticipated operational occurrences

Anticipated operating occurrences (AOOs) are Condition II events, as such, the regulatory design criteria require that these transients result in no plant damage. A strategy of both prevention and mitigation is incorporated into the design to assure that this objective is met. These include engineered safety features, core monitoring, and the reactor protection system.

Among the six LWR event categories listed above, the most significant AOOs to the thermal designer (limiting transients) are those in the undercooling and power distribution anomaly category. Notably, decreases in coolant system inventory are typically LOCAs, which are postulated accidents. Since core damage during an AOO must be precluded by design, system response to these events is relatively mild and uncomplicated.

With core damage precluded, the emphasis of AOO transient analysis is on the margins to specified acceptable fuel design limits (SAFDLs). The set of SAFDL figures-of-merit depend on the plant design. A list of SAFDLs include the departure from nucleate boiling ratio (DNBR) in PWRs, minimum critical power ratio (MCPR) in BWRs, fuel centerline temperature and core flow (including hydrodynamic flow instability), coolant enthalpy distribution and fuel rod cladding strain. By definition, satisfying the SAFDL (i.e., acceptance criteria) means that no core damage occurs.

Undercooling transients

Undercooling transients are those in which there is a decrease in the rate of heat removal from a failure on the secondary system in a PWR or in the power conversion or coolant feedwater system in a BWR. Typical transients of this nature are loss of load (turbine trip), increase in feedwater temperature, and loss of feedwater flow. In each of these cases, the degradation of secondary-side heat removal capability leads to a rise in the reactor coolant system pressure and temperature.

The loss-of-load transient is the most common of these events. Such events include load rejection, turbine trip, loss of condenser vacuum and inadvertent closing of a main steam isolation valve. The main characteristic of this transient is the sudden reduction in steam flow. This causes a rapid reduction in heat removal from the core, leading to a pressurization of the reactor coolant system. In both PWRs and BWRs, increased coolant temperature will decrease core reactivity and, hence, power. While the reduction in power can be to a level below that of the rate of heat removal, plant protection systems are designed to recognize the conditions of an under cooling event and initiate a reactor trip. The SAFDLs emphasized in analysis are the core DNBR, primary pressure, and steam generator pressure in PWRs.

Overcooling transients

Overcooling transients include those caused by an increase in feedwater flow, decrease in feedwater temperature, excessive load, and an inadvertent opening of a relief, safety, or dump valve. Since these events cause a decrease in the reactor coolant system temperature, both core reactivity and power increase. In addition to an increase in power level, the transient also gives rise to an initial decrease in pressure. A reactor scram may be initiated by high flux levels, high thermal power, or low reactor coolant system pressure. A conservative analysis of this transient is usually accomplished using the maximum moderator reactivity feedback and the minimum fuel temperature feedbacks. The SAFDL emphasized in this analysis is core DNBR in PWRs and MCPR in BWRs.

Core flow anomaly

The principal core flow anomaly DBEs are the loss of flow and hydrodynamic flow instability. In PWRs, the loss of flow DBE is generally the most limiting of all AOOs. Primary coolant flow may be reduced by the loss of a single or multiple reactor coolant pump. In these events, the core flow rate decreases. The reduced primary system flow rate degrades core heat transfer, resulting in increased reactor coolant system temperatures. The PWR SAFDL emphasized in this DBE is DNBR.

In BWRs, operation can become unstable under certain circumstances for neutronic or thermal-hydraulic reasons when operating with a mismatch of low core flow and high core power (March-Leuba et al., 1986). This BWR instability may be realized as a global power oscillation, a power oscillation that occurs regionally within the core (hence total core power varies very little), or as a density wave oscillation within individual fuel assemblies that result in large fluctuation of the assembly flow rate. Power oscillations occur because of reactor feedback from changes in coolant void fraction or density and/or moderator and fuel temperature. Density wave oscillations are primarily driven by fuel assembly pressure drop considerations.

Since in a BWR the coolant channels are isolated, a large void fraction in the core leads to a substantial void-power feedback. During normal operating conditions, the density reactivity and the fuel temperature (Doppler) reactivity are negative, which ensures that the reactor power remains stable. In nuclear power systems, instabilities are possible even with these negative feedback mechanisms, if the feedback gain or the phase lag is increased beyond some critical value. Experiments have shown that BWRs are susceptible to reactivity instabilities when operated at low flow and relatively high power levels (e.g., <30% flow and >50% power). Transient analysis of BWR instability events emphasizes the characterization of operation limits with respect to core flow.

Increase in reactor coolant inventory

The AOOs that lead to an increase in reactor coolant inventory include the inadvertent operation of the ECCS, malfunction of the chemical and volume control system (i.e., for coolant makeup and letdown control) in PWRs or a feedwater malfunction in BWRs.

The more serious concern for both PWRs and BWR is reactor coolant pressure. As coolant inventory increases, so does the reactor coolant system pressure. Like overcooling transient, if the injected coolant is significant cooler than the core inlet temperature, reactor power may also increase. The increase in power can lead to higher reactor coolant pressure. The transient is usually examined to show that the operator has time to end the accident before the pressurize increases above a relief or safety valve setpoint.

Reactivity and power distribution anomalies

The AOO reactivity transient involves the positive addition of reactivity in the reactor core. Consequently, core power and temperature increase either locally or core wide. Transients in this category result from control system failures, control element ejections or uncontrolled withdrawal, and variations in coolant/moderator temperature, void fraction or density. Other specific examples include control assembly misalignment (fail to insert), startup of inactive loop (i.e., overcooling), or a chemical volume control system malfunction, such as the inadvertent dilution of boron concentration in a PWR. The AOO reactivity transient generally involves the slow addition of core reactivity relative to those DBEs considered reactivity accidents. The SAFDL emphasized in the analysis of reactivity transients is enthalpy (energy) deposition in the fuel. Failure to preserve the SAFDL means that the rate of energy increase in the fuel could result in its failure.

Postulated accidents

Postulated accidents are Condition IV events that are not expected to occur during the life of a nuclear power plant. The occurrence of a postulated accident is expected to result in the release of fission products from the fuel or coolant system. The fission product release rate and total release inventory are equated to the potential radiological dose received by an occupational worker or an individual from the general public. The more common postulated accidents considered are drawn from the same general categories identified for AOOs; however, these are dominated by events described as decreases in system inventory, certain loss-of-flow events, and reactivity initiated accidents. In the licensing of nuclear power plants, postulated accidents also extend to fuel handling accidents.

Loss-of-coolant accident (LOCA)

A LOCA is any decrease in system inventory due to inadvertent valve opening or breach of the reactor coolant system pressure boundary. For very minor leaks, the makeup system may be able to make up the loss. If so, there may be no reactor scram. For an inadvertent valve opening, the charging system probably cannot keep pace. The letdown system would be isolated and the event probably terminated by low pressurizer level (in a PWR) or pressure. The class of LOCA events also includes scenarios involving open safety or relief valve that fail to close on reduced pressure.

The most serious accident generally considered in the evaluation of a nuclear power plants design-basis, often referred to as the Maximum Hypothetical Accident, is the double-ended rupture of a main coolant pipe. If such an unlikely accident were to occur, the course of expected events would be (Tong and Weisman, 1996):

- (1) Subcooled blowdown: The system is rapidly depressurized until the vapor pressure of the coolant is reached. The reactor protection system will signal a reactor trip, most likely on low pressure. Voiding in the core region will also contribute to a cessation of fission.
- (2) Saturated blowdown: after system pressure falls to the level of coolant vapor pressure, steam voids are formed. Sonic velocity is drastically reduced, pressure waves are damped out, and choked flow occurs at the break. The length of this period depends on the location and size of the break. During this period, the fuel rods are cooled by fluid in the reactor core. Initially, high forced convection or nucleate boiling heat transfer coefficients prevail. As fluid enthalpy increases, the boiling crisis can be reached, leading to a marked reduction in core cooling. Cladding temperature rise is reduced as the time between blowdown initiation and boiling crisis is increased.
To extend the period during which the core is well cooled, an ECCS is provided. When the primary system pressure falls to a predetermined level, a large quantity of borated coolant water is injected from high-pressure accumulators. In most PWR designs, bottom flooding is used and ECCS water enters the reactor vessel through the downcomer.
- (3) Dry period: after the accumulator inventory is exhausted, continued blowdown leads to a condition where the liquid, or rather the liquid-steam froth, falls below the top of the core. When the froth level is above the bottom of the core, the dry portion is cooled by steam generated in the lower region. When the froth level drops below the bottom of the core, the only core cooling is by radiation to the surrounding structure and by convection and radiation to the small amount of steam generated by froth contact with the vessel wall. During this period, fuel rod cladding temperatures are expected to rise to a level at which the zirconium-based cladding reacts with steam appreciably. The heat produced by this exothermic reaction must be considered in assessing the maximum temperature rise.
- (4) Vessel reflood: after the accumulator injection has stopped and system pressure has been further reduced, high flow pumps of the ECCS system add water to the reactor vessel to recover the core. Since most designs call for bottom-up reflood of the core

region, substantially improved cooling does not result until the coolant level reaches the bottom of the core. The steam produced from quenching the lower portion of the fuel rods flows upward and cools the upper portion of the core. This steam cooling generally limits the maximum temperature reached by the cladding. The water from ECCS pumps gradually refills the core; the transient is terminated when the vessel is refilled. Provision is made for the subsequent addition of water at a low rate to replace that lost through boiloff.

Steam line rupture

Steam line ruptures (SLR) are postulated accidents involving the rupture of a secondary system steam line in a PWR or the main steam line in a BWR. In addition to the breach of the reactor coolant system pressure boundary, they are also considered overcooling transients and the increase in reactivity from overcooling is modeled. The most serious of these accidents is a main steam line break based on the assumption of an instantaneous guillotine rupture.

When an SLR occurs, there is a sudden increase in steam flow. In a PWR, the rapid cooling associated with the SLR occurs via the steam generator. BWRs will cool down from the rapid depressurization of the reactor coolant system. If unmitigated, the profile of the SLR in a BWR aligns with that described previously for a LOCA. In PWRs, the rapid cooling of the secondary system causes the primary system to cool and depressurize until the secondary system completely depressurizes. In either LWR design, the reactor protection system initiates a reactor trip on either low reactor coolant system pressure or liquid level (steam generator in PWRs or the core in BWRs). Closure of the main steam isolation valve close mitigates the blowdown in many scenarios. In PWRs, the SLR is often difficult to distinguish from a LOCA.

Containment response to a LOCA or SLR

LOCAs and certain SLRs directly expel coolant inventory into the containment. The depressurization of the reactor coolant system (or the secondary cooling system in PWRs) in these events can challenge the integrity of the steel and/or concrete containment that encloses the reactor coolant system. As such, the design criteria on containments is that they withstand the loads imposed by LOCAs and SLRs and contain any fission products that escape the reactor coolant system pressure boundary.

The mass and energy leaving the reactor coolant system in both LOCAs and SLR has an immediate effect on the containment pressure and temperature. The impact on the containment is compounded as the air that was resident in the containment warms and expands due to the addition of the hot steam and water. The short-term effect on containment pressure and temperature is mitigated passively by condensation of the steam on the containment walls. As such, peak pressure and temperature occurs very soon after the initiation of the LOCA or SLR.

After the temperature of the structures within the containment equilibrate with the atmosphere, the pressure and temperature stabilize. In the SLR, this is the nominal conclusion of the containment response. In contrast, the recovery from a LOCA can last several days depending on the mitigation strategy. Most long-term cooling scenarios for LOCA mitigation utilize water first from storage water tanks and then switch to water residing in the containment sump. Following the switchover to the sump, water is recycled back to the reactor coolant system. If the sump water is not cooled or if other mechanisms are not used remove decay heat, the continued boil-off of water cooling the core can lead to a repressurization of the containment (Lane and Franz, 2019; Sharpe, 2021).

Reactivity initiated accidents

Reactivity initiated accidents (RIAs) resemble reactivity transients but involve larger and faster reactivity changes. Control rod ejection accidents (REAs) in PWRs and Russian VVERs and control rod drop accidents (CRDAs) in BWRs occur by mechanical failure of the control rod driving mechanism or its housing. Since the reactivity rates and the resulting power transients are much faster than the limits imposed for reactivity transients, these DBEs are classified as accidents. The immediate consequence of a RIA is a fast rise of power and fuel temperatures. The power excursion may lead to failure of fuel rods and the release of radioactive material into the reactor coolant system. The damage mechanisms are all related to high temperature and the degree of fuel damage correlates well with the peak value of fuel pellet specific enthalpy.

As described in section “Design-Basis Event Characterization,” ATWS are unique reactivity initiated events that involve an AOO compounded by a failure in the normal reactor protection system to initiate a timely reactor trip (i.e., scram). This postulated complete failure of the required single-failure proof reactor protection system takes the scenario beyond the definition of DBE. Nonetheless, it is considered a special category of events that must be evaluated with analysis method procedures and acceptance criteria unique to both AOOs and postulated accidents.

Radiological evaluations

Radiological evaluations for DBEs and DBAs are conducted whenever such an event or accident is determined to release radioactivity. The release of radioactivity occurs anytime there is a release of primary and/or secondary coolant (the latter only for

PWRs). The release of coolant involves, as a minimum, the radioactivity dissolved in the coolant. It can also involve activity found in the pellet/cladding gap within the fuel rod (the so-called “gap activity”), activity released from localized fuel melting (due to a localized reactivity insertion), or activity released from generalized fuel overheating and melting due to a sustained loss of core cooling.

The evaluation of radiological consequences involves calculations for post-accident radiological dose to individuals from exposure to sources of radioactivity (Metcalf and Chang, 2019). These evaluations consider shielding, leakage rates, and the transport of fission products offsite. As with SAFDLs or LOCA acceptance criteria, the calculation of the effective dose from radiation is compared to regulatory acceptance criteria to assess the adequacy of dose mitigation features incorporated in a nuclear power plant. Bley (2021) details the safety and licensing requirements and acceptance criteria as they relate to radiological measures.

Licensing considerations related to transient analysis

Transient and accident analysis as described in this chapter demonstrates part of a nuclear power plant’s overall safety mission against the breadth of applicable regulation and regulatory guidance (McIntyre, 2019). The set of events selected to satisfy these requirements define a nuclear power plants design-basis envelope. The design-basis envelope is the collection of the requirements and conditions that serve as the reference point for a design’s safety case throughout the lifecycle of a plant, beginning with the design conceptualization and development, deployment and operation, and, lastly, decommissioning. Organizations involved in the engineering and operations of nuclear power plants establish and implement processes to control the design and design changes of items that are subject to the quality assurance requirements set by national nuclear safety authorities.

Transient and accident analyses are initiated to establish the facility’s hazards and operability characteristics. Credible transients and accidents are identified per methods outlined in Section “Design-Basis Event Characterization” that emphasize a plant’s critical safety functions, distinguishing which structures, systems and components in the plant are to be considered safety-related (and which are not). Among these will be one or more events considered the maximum hypothetical accident (MHA). Safety analyses of the set of transients and accidents and the MHA, in particular, provide the analytical basis supporting the plant’s technical specifications—the statement of relevant limits of operation associated with the design-basis envelope. The principal measure derived from these analyses is the effective dose from radiation, but, as noted in Section “Deterministic and Best-Estimate Analysis Methods,” other thermal-hydraulic measures are typically often used as surrogates to effective dose.

Analysis, along with physical testing, are essential parts of controlling the design-basis envelope. As the lifecycle of a nuclear power evolves, so must the analyses performed, verifying the safety of a nuclear power plant. This means that this set of safety analyses is performed many times both during and following the design phases to account for the refinement and changes to the equipment’s performance parameters and system configurations.

Glossary

Containment building The air-tight structure, which houses a nuclear reactor core vessel, pressurizer, reactor coolant pumps, steam generators, and other equipment or piping that might otherwise release fission products to the environment in the event of an accident. Such enclosures are usually dome-shaped and made of steel-reinforced concrete. The term applies for both PWR's and BWR's.

Decay heat The inherent heat produced by the decay of radioactive fission products after a reactor has been shut down.

Drywell The portion of a BWR containment in the immediate vicinity around the reactor system which accepts reactor coolant discharged during a postulated LOCA and routes the discharge to the suppression pool.

Emergency core cooling system (ECCS) An Engineered Safety Feature system responsible for makeup of cooling water into the reactor core following postulated LOCAs or other occurrences.

Engineered safety Nuclear plant systems, structures, and components designed to mitigate.

Features The consequences of postulated accidents.

Loss of coolant accident(s) (LOCA) Postulated accidents resulting from the loss of reactor coolant at a rate in excess of the capability of the reactor coolant makeup system from breaks in the reactor coolant pressure boundary, up to and including a break equivalent in size to the double-ended rupture of the largest pipe of the reactor coolant system.

Source term Types and amounts of radioactive or hazardous material released to the environment following an accident.

Suppression pool A large pool of water that suppresses pressure and temperature increase in the free volume of the BWR containment by virtue of water's large heat capacity. The pool also serves as a source of water for long-term core cooling.

Ultimate heat sink The structures, components, and environmental conditions serving to absorb and dissipate plant heat loads after normal or emergency reactor shutdown.

Wetwell The portion of a BWR containment enclosing and above the free surface of the suppression pool that accepts non-condensable gas displaced from the drywell during a postulated LOCA.

Role of containment

Nuclear power reactors are designed and operated with Engineered Safety Features (Lutz and Williamson, 2021) having active or passive attributes aiming to protect against adverse consequences to people and the environment arising from highly unlikely postulated accidents. Radioactive material is continually produced during power generation as fission reactions consume fuel in the core, producing so-called radioactive fission products comprising the source term material which must be retained by physical barriers and Engineered Safety Features of the plant. For standard power reactors presently in service, the solid fuel form serves as a first barrier retaining the radioactive source term, while further material barriers are provided by structural components of the fuel and core- namely the cladding tubes containing solid fuel, and the vessel and piping boundaries of the normally pressurized reactor coolant system. As a standard reactor core operates at elevated temperature and pressure for optimal thermal efficiency and associated plant economic performance, a significant amount of stored energy is naturally held in the fuel, core structure, and coolant. Additional energy from decay heat is produced during power generation and notably persists at a decreasing rate even after fission power generation ceases (reactor shutdown). Management and removal of this stored energy and decay heat during postulated accident sequences determines the design requirements and specifications placed upon several Engineered Safety Features, such as the

Emergency Core Cooling System (ECCS) for controlled removal of core heat when the normal coolant pathway becomes compromised in a postulated Loss of Coolant Accident (LOCA).

The final physical barrier serving also an Engineered Safety Feature required by general design criteria implemented by most nuclear regulatory authorities (Hamon 2021a)—encloses the entire nuclear power reactor system and prevents release of radioactive source term material in quantities having unacceptable effects on people and the environment. This containment barrier normally includes a substantially large and robust structure (the Containment Building) with associated systems functioning to preserve structural integrity throughout postulated accident scenarios. Possible rapid and violent release of stored energy from the core and coolant during a LOCA is a key internal challenge to containment structural integrity, as is longer term (several minutes up to many days) redistribution and removal of decay heat, radioactive source term material, and other reaction products resulting from interacting materials (e.g., hydrogen generation from zirconium metal-water reactions). The containment must handle these energy and material challenges while maintaining an essentially leak-tight boundary to prevent any material release. The Containment Building must also be suitably robust to survive intact many possible hazards from external sources, such as an earthquake, hurricane, tornado, or airplane strike.

Containment structure and system design requirements for nuclear power reactors are devised from and demonstrated by comprehensive engineering analysis and simulation. These steps provide reasonable assurance that any release of source term material remains within acceptable limits established by the regulatory authority. Accident scenarios selected for analysis are established by the reactor system design basis and chosen from postulated yet credible scenarios with severe consequences. For example, energy discharge into containment by postulated design basis LOCA events would inevitably cause temperature and pressure to increase within the enclosure, so that the structure analysis must demonstrate resistance to static and dynamic pressure, temperature, and fluid flow loadings. Eventual cooling of the core and containment by active coolant injection or passive heat removal systems may cause the containment pressure to fall below atmospheric pressure. Cooling water collects in the lower reaches of the containment structure, serving as a sump for possible recirculation into the core or containment via sprays, though perhaps limited somewhat by the available inlet pressure for the associated circulating pumps. Possible relocation of radioactive source term material following core heatup requires measures to clean the containment atmosphere at these varying pressure and temperature conditions. Scrubbing of radioactive material from the containment atmosphere would be performed to reduce amounts potentially leaked to the environment. Removal of excessive hydrogen also requires a specific system designed to alleviate the risk of combustion. All equipment required to perform these safety-related functions must be shown to operate and survive conditions for the event duration, thereby proving so-called equipment environment qualification. Practical plant operation utilizes several penetrations into the containment structure, requiring systems to isolate these openings during a postulated accident, perhaps even incorporating a secondary containment structure. Clearly, the many design requirements for containment and core cooling systems are rather complex and deeply intertwined for mitigating full accident sequences.

Most nuclear reactors deployed worldwide use water for the heat transfer that enables power generation, with the nuclear system either preventing boiling in the core (the Pressurized Water Reactor—PWR) (Brown, 2021) or allowing steam production by boiling in the core (the Boiling Water Reactor—BWR) (Hamon, 2021b). Containment systems for these water reactors have similar functional needs yet have different characteristics to address these needs. A brief overview of these characteristics for PWR's and BWR's are provided herein. Other less common existing or proposed reactor types may use a heat transfer medium other than water, however this article will only consider containments for water-cooled reactor systems.

PWR containment characteristics

The highly energetic discharge of hot ($\sim 288^\circ\text{C}/550^\circ\text{F}$) and pressurized ($\sim 15.5\text{ MPa-g}/2250\text{ psig}$) reactor coolant into containment during postulated LOCA's must be accommodated by the very large free volume surrounding reactor components (vessel, steam generators, pressurizer, piping, etc.). A correspondingly large structure composed of reinforced concrete, several feet thick in places and often sealed with a steel liner, encloses the large volume and includes interconnected rooms. This very large structure is a dominant characteristic of PWR containments that are designed and built to be self-supporting, but also to handle loads by internal and external hazards. Fig. 1A shows a representation of a PWR containment with the large free space around the primary reactor system. In addition to the expansive volume, large internal surface areas are available for condensing the discharged coolant, and generally a spray system is used to cool the containment atmosphere by evaporation of small water droplets. Performance of these heat transfer mechanisms are evaluated with conservative assumptions to ensure containment design temperature and pressure are not exceeded. Clearly the size and robustness of the containment systems and structure are important factors in the total capital cost of a nuclear power plant. Various PWR containment configurations have evolved in an attempt to balance plant costs while meeting specified general design criteria. Most PWR plants have one of four design variants implemented: dry ambient, dry sub-atmospheric, ice condenser, and passively cooled.

Dry containments rely on coolant expansion into the large volume filled with ambient air ($\sim 0.103\text{ MPa}/15\text{ psia}$), or sub-atmospheric held at partial vacuum ($\sim 0.069\text{ MPa}/10\text{ psia}$), to limit the peak atmospheric pressure during all LOCA scenarios, including the challenging scenarios of a break in a reactor recirculation pump suction line or a main steam line. Consider as an example the PWR plant containment as displayed in Fig. 1B. With a rated thermal power of 3645 MWth and dry ambient containment free airspace volume at $7.87\text{E}04\text{ m}^3$ ($2.78\text{E}6\text{ ft}^3$), the characteristic discharge capacity is around $21.6\text{ m}^3/\text{MWth}$ ($760\text{ ft}^3/\text{MWth}$) and peak design pressure is 0.41 MPa-g (60 psig). A representative PWR plant operating at 2940 MWth with

Fig. 1 (A) General PWR containment building layout and relative scale for (B) dry ambient/sub-atmospheric, (C) ice condenser, and (D) passively cooled containments. (A: <https://www.nuclear-power.net/nuclear-power-plant/containment-building/>; B: <https://www.nrc.gov/reading-rm/basic-ref/students/for-educators/04.pdf>; C: <https://www.nuclear-power.net/nuclear-power-plant/containment-building/>; D: <https://www.westinghousenuclear.com/Portals/5/Other%20PDFs/UKP-GW-GL-793NP-sm.pdf>).

a dry sub-atmospheric containment free airspace volume of $5.17\text{E}04\text{ m}^3$ ($1.825\text{E}6\text{ ft}^3$) has a roughly similar yet smaller characteristic discharge capacity of $17.5\text{ m}^3/\text{MWth}$ ($620\text{ ft}^3/\text{MWth}$) and a lower peak design pressure of 0.31 MPa-g (45 psig). A somewhat smaller relative structure size is therefore possible with the dry sub-atmospheric containment compared to dry ambient, however the cost of additional equipment to maintain the partially evacuated atmosphere may offset a portion of the potential capital savings. [Note: the representative values for containment volume, reactor power, and design pressure (expressed in absolute, gauge (g), or differential (d)) presented within this article were obtained from public documents and provided, for example, in the Final Safety Analysis Report of operating plants. See Hamon 2021A for additional information.]

An alternative PWR containment design implemented to further reduce size and cost incorporates beds of ice over which the containment atmosphere flows and cools during a LOCA scenario. Fig. 1C indicates the relative size and annular location of Ice Condenser (IC) equipment in this containment type. Large sections of ice doped with boron (for eventual melting and injection

into the core) are continually refrigerated during normal operation and provide rapid condensation of discharge from postulated LOCA scenarios, thereby reducing possible peak containment atmosphere pressures and temperatures. For comparison, a representative PWR plant rated at 3411 MWth with an ice condenser containment free airspace volume of $3.31\text{E}04\text{ m}^3$ ($1.17\text{E}6\text{ ft}^3$) has a smaller still characteristic discharge capacity of $9.34\text{ m}^3/\text{MWth}$ ($330\text{ ft}^3/\text{MWth}$) but a much-reduced peak design pressure of 0.1 MPa-g (15 psig). Cost savings may be found with reduced structural requirements, but the tradeoff comes by way of a relatively complex refrigeration system. Furthermore, operational challenges may occur during refueling with a relatively smaller space available for maneuvering fuel and equipment.

A more recent PWR containment design approach targets reduced reliance on active equipment by using natural forces for cooling. The passively cooled containment system (PCCS) relies upon gravity to supply a large inventory of water for heat removal rather than pumps requiring electric power. Natural circulation of air on the outside of the containment draws heat out of the structure without use of an active system. Fig. 1D shows the layout of passive components and systems for containment cooling, with the large water inventory in the PCCS water tank situated above the containment structure. The passively cooled containment configuration requires a characteristic discharge capacity of $\sim 17.3\text{ m}^3/\text{MWth}$ ($610\text{ ft}^3/\text{MWth}$) and maintains a design pressure of 0.41 MPa-g (59 psig), similar to the dry ambient containments, but without the associated costs of safety-related active containment cooling system components.

BWR containment characteristics

Nuclear reactors that boil water and generate steam in the core are designed to operate at lower pressure ($\sim 6.89\text{ MPa-g}/1000\text{ psig}$) and directly transport reactor coolant to the steam turbine for power generation. Though somewhat less than a PWR, a similarly rated BWR also retains a tremendous amount of stored energy and decay heat that must be accommodated within containment for postulated LOCA scenarios. Components such as steam generators and a pressurizer are not used in the BWR, thus a comparatively smaller space is needed for reactor components within containment. An alternative approach to the dry containment is implemented in part to further reduce containment size and hence possible savings in plant capital costs. Containment size reduction is achieved by using a large inventory of water connected by a series of flow conduits, or vents, to the free volume surrounding the reactor system—a space generally referred to as the drywell. Heat transfer and steam condensation within the water pool suppresses the maximum pressures and temperatures of the containment atmosphere following a LOCA discharge. Non-condensable gas present in the drywell is pushed into the water suppression pool then passes into the enclosed free space above the pool, referred to as the wetwell. Active heat transfer systems supply pool water to cool the core (ECCS), drywell, and wetwell for longer term removal of decay heat. All modern BWR's utilize some variant of this pressure suppression containment approach, with change to vent configuration and structure being a key difference. Three principal containment variations rapidly evolved throughout the history of BWR plant design, each being developed, tested, and certified by the General Electric Company.

The first variant, referred to as the Mark I BWR containment, incorporates the suppression pool in a large steel tank of toroidal geometry connected by several sizeable pipes to the drywell. Fig. 2A indicates the cross-section of the torus at the lower section of the reactor building, along with the layout of vent pipes connecting to the drywell and the vent ring header within the wetwell. Projecting vertically downward from the ring header and submerged into the suppression pool are numerous downcomer pipes that complete the vent system. The upper drywell region provides a relatively tight fit to the reactor vessel, yet enlargement in the lower region gives space for expansion and routing of LOCA discharge flow into the containment vents. This configuration is colloquially termed the “inverted lightbulb” drywell (perhaps in deference to Thomas Edison, founder of General Electric and generally credited inventor of the incandescent lightbulb!). Fig. 2B shows an isometric perspective for scale and layout of the reactor system, Mark I containment drywell, wetwell, and vent systems, along with the surrounding reactor building serving as a secondary containment boundary. For comparison to PWR containments and BWR Mark II and III containments, a representative BWR power reactor rated at 2923 MWth with a Mark I containment has a drywell free volume of 4644 m^3 ($164,000\text{ ft}^3$), a corresponding wetwell free space volume of 3483 m^3 ($123,000\text{ ft}^3$), and a suppression pool volume of 2492 m^3 ($88,000\text{ ft}^3$ or $\sim 660,000\text{ gal}$). Assuming robustness of structure holding the pool of water is similar to the structure comprising the drywell structure, the total representative Mark I containment volume is $10,620\text{ m}^3$ ($375,000\text{ ft}^3$), giving a characteristic discharge capacity of $3.62\text{ m}^3/\text{MWth}$ ($128\text{ ft}^3/\text{MWth}$), and reflecting the general effectiveness of the water suppression compared to dry containment. Although the structure is overall smaller compared to the PWR containments, the design pressure of the Mark I BWR containment remains quite high at $\sim 0.43\text{ MPa-g}$ (62 psig) for both the drywell and wetwell. The relatively compact size of the drywell and wetwell volumes facilitates use of a nitrogen-inerted atmosphere to reduce the likelihood of hydrogen combustion from metal-water reaction postulated for severe LOCA's. Some additional complexity remains with the structural requirements of the vent system, since LOCA discharge forces result in rather large blowdown, clearing, and quenching/chugging loads from pool water at the exit of downcomer pipes—an area for improvement in BWR containment design evolution that in part led to the Mark II containment.

With increased BWR reactor size and power output, the Mark II containment allows more water volume available for pressure suppression. Fig. 2C shows the Mark II configuration including the tapered drywell overtop a large water pool separated by a concrete deck. The reactor vessel sits high in the drywell on a concrete pedestal that continues through the wetwell and onto the containment building basemat. Rather than a toroidal tank, the suppression pool is held within a cylindrical concrete chamber and fills into the lower interior section of the reactor pedestal. Drywell and wetwell interior surfaces are lined with steel, and the outer boundaries housed within the reactor building serving as secondary containment. The simplified vent system uses many

Fig. 2 Pressure suppression containment structure layout and evolution applied to the General Electric line of BWR's. (A) Mark I containment outlining the "inverted lightbulb" shape of the steel-lined drywell and toroidal structure of the wetwell. Reactor and containment component layout for (B) Mark I, (C) Mark II, (D) Mark III BWR containments. (A: <https://www.nuclear-power.net/nuclear-power-plant/containment-building/>; B: <https://www.nrc.gov/reading-rm/basic-ref/students/for-educators/03.pdf>; C: <https://www.nrc.gov/reading-rm/basic-ref/students/for-educators/03.pdf>; D: <https://www.nrc.gov/reading-rm/basic-ref/students/for-educators/03.pdf>).

downcomer pipes penetrating the drywell deck and directly connects the drywell atmosphere to the suppression pool. Thrust and lateral loads are eased somewhat through axisymmetric reactions, although the downcomer length requires additional buttressed support. Like the Mark I containment, the Mark II containment is also inerted with nitrogen gas. A representative BWR plant rated at 3546 MWth has a drywell free volume of 6513 m³ (230,000 ft³), a wetwell free volume of 4700 m³ (166,000 ft³), and suppression chamber water volume of 3680 m³ (130,000 ft³ or ~975,000 gal). The total representative Mark II containment volume is thus

14,895 m³ (526,000 ft³), giving a characteristic discharge capacity of 4.19 m³/MWth (148 ft³/MWth), slightly higher than the Mark I containment. A comparatively lower design pressure of 0.31 MPa (45 psig) is allowed, however, with the caveat that the pressure differential between the drywell to wetwell is no more than 0.17 MPa-d (25 psid), and 0.34 MPa-d (5 psid) from wetwell to drywell, to ensure structural integrity of the drywell deck. Though the simplified downcomers were an improvement, discharge loads at the downcomer pipe exit could see further reduction with a completely different venting concept.

A third, or Mark III, BWR containment design variant evolved in part to relieve the need for downcomer pipes and associated structures in handling LOCA discharge and quenching loads. The Mark III containment also leverages features of the dry ambient containment concept with a very large available free volume but quite low design pressure—attempting to marry the best of both dry and pressure suppression containment approaches. Fig. 2D gives a view Mark III containment with reactor component placement, pool location, and the large containment structure and free airspace. Rather than incorporating header pipes and downcomer vents, the Mark III configuration has the drywell volume interface the suppression pool by way of an annular weir wall extending upward from the basemat and placed just inside the drywell wall. Water from the suppression pool fills the annular gap between the weir wall and drywell wall by three vertical rows of horizontal vent holes bored into and distributed around the azimuth of the drywell wall. The outer perimeter of the annular suppression pool is bound by the containment vessel inner wall and the containment airspace volume above. LOCA discharge mass and energy into the drywell will displace the water in the narrow annulus and push into the horizontal vents, with each row of vents uncovering at different times during the discharge event. With horizontal vents configured in this fashion, discrete structural loads are more smoothly distributed compared to those for a downcomer vent pipe. The containment also houses a large volume of water in an upper pool, along with a large pool for refueling, that may serve as a water source for ECCS or containment spray, but not directly available for pressure suppression. A BWR plant rated at 4408 MWth with a Mark III containment includes a drywell free volume of 6682 m³ (236,000 ft³), a containment free airspace volume of 3.375E4 m³ (1.192E6 ft³), and suppression pool water volume of 3936 m³ (139,000 ft³) (~1000,000 gal), resulting in a total available volume for containment of 4.45E4 m³ (1.57E6 ft³). The resulting characteristic discharge capacity is 10 m³/MWth (355 ft³/MWth)—the largest characteristic size for the BWR containments—and comparable to the PWR ice condenser containment. A distinctive reduction is achieved, however, for the Mark III containment design pressure of 0.10 MPa-g (15 psig), comparatively reducing design requirements for the large containment structure. The drywell design pressure is similar but slightly reduced at 0.28 MPa (40 psig) relative to the Mark II drywell design pressure (0.31 MPa-g/45 psig). Similar to the PWR dry ambient containment, the large free volume of the Mark III containment makes impractical any inerting with nitrogen gas.

Further evolution of the BWR containment has occurred for the Advanced Boiling Water Reactor (ABWR) and the Economic Simplified Boiling Water Reactor (ESBWR), but each implement features similar to those of Mark II and Mark III. Very few ABWR's and no ESBWR's have been deployed to date, thus further consideration is not provided herein for these designs.

Common engineered safety features

Nuclear power reactors require systems that interface or utilize containment features to perform a given safety function, such as cooling the core or maintaining integrity of the containment structure. Similar functions are required for both PWR and BWR containments, and they may be considered generally applicable to each variant. General design criteria for containments are satisfied by Engineered Safety Features implemented in various systems affecting the containment atmosphere, cooling water inventory, and control of radioactive source term material. A few of these systems are briefly described below, with focus on the active systems (requiring electric power and operator action) that are in use at the predominant nuclear power plants.

Containment heat removal systems

Energy released from the reactor core during postulated LOCA scenarios acts over the long term (beyond the blowdown and pressure reduction/suppression period) to heat the containment atmosphere, structure, and components. Removal of this heat requires cooling systems to ensure design specifications are not exceeded. Fan coolers are available to circulate the containment gaseous atmosphere through heat exchangers cooled, for example, by plant service water into the site ultimate heat sink. These fan coolers may also be used during normal operations to sustain containment temperature within specifications. A containment spray system is implemented to actively cool the containment atmosphere with small water droplets that are very effective for evaporative cooling. A source of water for the containment spray system is the suppression pool inventory in BWR's and the containment sump for PWR's (supplied, for example, by condensed reactor coolant, injected makeup water for core cooling, and return of unevaporated containment spray). Residual heat (the combination of stored energy and decay heat) removal systems also provide containment cooling with water sourced from the ECCS or suppression pool.

Source term material control systems

Radioactive source term material transported during postulated accident scenarios that breach the first two barriers (cladding failure and reactor pressure boundary failure) shall be retained with minimal release from containment. Several safety-rated systems work in concert to prevent such release. The containment isolation system acts to prevent leakage from fluid systems by use of isolation valves, interlocks, or other barriers for all pipes which penetrate or pass-through containment except those needed for accident

response. Components of the isolation system are triggered by instrumentation monitoring reactor conditions as well as containment atmosphere conditions and operate during anticipated abnormal conditions as well as postulated accidents. Prevention of long-term containment pressurization is often accomplished with a venting system that may incorporate filtration, allowing greater flexibility for operators responding to accident conditions. Many nuclear plants incorporate a secondary containment structure (often as the reactor building) that may collect and clean source term material that may leak from the primary containment structure. Requirements are established to periodically test leakage from both primary and secondary containments to assure performance of the isolation and venting components. Relocation and removal of radioactive source term material within containment improves performance of these components in retaining the material. This role is performed by containment atmosphere cleanup systems that generally include in-containment recirculation system (fan coolers), stand-by gas treatment systems, and air-cleaning systems for connected rooms. Containment spray, for example, provides an important feature to capture radioactive gases (primarily iodine) and aerosols in the containment atmosphere or wash debris from surfaces within containment upon which radioactive debris has settled.

Combustion control systems

Combustible gases may be generated during postulated accident scenarios where metal-water reactions (primarily from zirconium) generate and release hydrogen gas when core components overheat. In the highly unlikely, yet more severe, postulated accidents (extending beyond design basis accidents), molten core material may interact with concrete in the containment structure to produce combustible hydrogen, carbon monoxide, and oxygen gases. Mixing of combustible gases with oxygen in the containment airspace (for non-inerted containments) may undergo exothermic reactions sufficiently rapid or explosive thereby resulting in containment breach, or more likely, a substantial increase in leakage beyond the capacity of the containment isolation system. Mitigation of possible hydrogen explosions is achieved by deploying controlled hydrogen reaction systems, generally in the form of passive autocatalytic recombiners (PAR) and hydrogen igniters. While these components are effective in locally controlling hydrogen concentration, complications with predictions of combustible gas generation rate, gas mixing, dead-space volumes, and hot surfaces requires careful attention to determine their distribution within containment.

Conclusion

The high degree of importance given to the final barrier protecting people and the environment from postulated accidents at nuclear power plants is reflected in the size, complexity, and associated cost of the containment systems, structures, and components. With Engineered Safety Features, containment is categorized as a safety-related system with correspondingly high attention provided by regulatory authorities in certifying plant construction and operation. A number of key characteristics have been described and compared here, giving a brief introduction to some of the concepts considered, evaluated, and demonstrated in order to achieve regulatory approval. This discussion begins to only scratch the surface of containment performance, with many excellent resources available for further pursuit by the interested reader. Only a few resources are listed below, recognizing there are many, many more excellent treatises available.

Glossary

Advanced Light Water Reactor Advanced LWR (ALWR) is a reactor, BWR or PWR, which meets the requirements of the ALWR program, U.S. and international utility sponsored effort, managed by the Electric Power Research Institute, to establish the technical foundation for the design of the next generation of nuclear power plants.

Air Handling Units A component in a HVAC system consisting of an inlet area, filters (as specified by the system), heating elements (coils), cooling coils (as required) and the respective fans (supply or exhaust).

As Low as Reasonably Achievable As defined in Title 10, Section 20.1003, of the Code of Federal Regulations (10 CFR 20.1003), The acronym, As Low As Reasonably Achievable (ALARA) means making every reasonable effort to maintain exposures to ionizing radiation as far below the dose limits as practical, consistent with the purpose for which the licensed activity is undertaken, taking into account the state of technology, the economics of improvements in relation to state of technology, the economics of improvements in relation to benefits to the public health and safety, and other societal and socioeconomic considerations, and in relation to utilization of nuclear energy and licensed materials in the public interest.

Auxiliary Boiler Steam System The Auxiliary Boiler System (ABS) consists of package boilers. During plant startup and shutdown and at any other time when insufficient main steam or extraction steam is available, the ABS can provide the necessary steam at sufficient pressure to the various equipment items such as; the feedwater system, to provide hot water during plant startup when decay heat is not present or is insufficient on its own to startup the plant in a timely manner, the Steam Jet Air Ejectors, to maintain the motive power required to perform a continuous evacuation of the non-condensable gasses from the Main Condenser and to the Offgas System in a BWR, the Turbine Gland Sealing System, to allow the Main Condenser to

reach vacuum; Preoperational testing of Offgas System equipment; and evaporation of liquid nitrogen for inserting of the Containment.

Chilled Water System (CWS) Consists of redundant independent subsystems that do not perform safety class functions. The CWS provides chilled water to the cooling coils of air conditioning units and other coolers in the nuclear island and the primary containment. Each subsystem would consist of redundant 100% capacity, independent loops with crossties between the chilled water piping.

Condensate and Feedwater System (C&FS) Receives condensate from the condenser hotwell(s), supplies condensate to the condensate purification system, and delivers high purity feedwater (FW) to the reactor, at the required flow rate, pressure and temperature. The C&FS does not perform, ensure or support any safety-related function, and thus, has no safety design basis.

Condensate Storage and Demineralized Water Transfer System Consists of redundant 100% capacity pumps and lines taking suction from one storage tank that is the normal source of water for makeup to selected plant systems. These systems are used for storage of makeup water and excess condensate rejected from the condensate & feedwater systems and the condenser hot well. These systems do not provide any safety class functions.

Design Basis Accident (DBA) Design basis accidents are postulated accidents used in the design to establish the acceptable performance requirements of the structures, systems, and components.

Emergency Core Cooling System (ECCS) The ECCS shall provide abundant core cooling. The system safety function shall be to transfer heat from the reactor core following any loss of reactor coolant at a rate so that fuel and clad damage will not interfere with continued effective core cooling.

Engineered Safety Features The design and functional requirements of engineered safety features (ESF) of the plant are provided to mitigate the consequences of postulated accidents. The ESF consist of containment systems, core cooling systems, habitability systems, and fission product removal and control systems.

Equipment Drain/Floor Drain Systems (EFDS) Collects waste liquids from their point of origin and transfers them to a suitable processing or disposal system. The Reactor Coolant Pressure Boundary leakage detection systems utilize features of the EFDS to provide a means of detecting and, to the extent practical, identifying the source of the reactor coolant leakage.

Evolutionary plant The evolutionary plant is envisioned as a large unit, employing substantial simplifications and improvements in plant safety systems and instrumentation and control systems. It is a direct descendent of today's ALWRs and its safety systems and regulatory base largely follow conventional approaches.

Instrument and Service Air Systems Are compressed gas systems which also include the Containment Inserting System (CIS) and the High Pressure Nitrogen Supply System (HPNSS). The CIS and the HPNSS provide nitrogen gas for instruments and valve operators within the inserted containment. Compressed air operated components having safety-related functions, either have safety-related accumulators or are fail-safe and do not rely on any of the compressed air systems to perform these functions.

Light Water Reactor LWRs are power reactors that are cooled and moderated with ordinary water. There are two basic types: the PWR and the BWR.

Loss of Preferred Power (LOPP) The offsite power system is referred to in industry standards and regulatory guides (RGs) as the "preferred power system." The preferred power supply interfaces with an alternate ac (AAC) power source for safe shutdown in the event of a station blackout (SBO) (non-DBA).

Quality Assurance Quality assurance (QA) comprises all planned and systematic actions that are necessary to provide adequate confidence that a structure, system, or component will perform satisfactorily in service.

Reactivity A term expressing the departure of a reactor system from criticality. A positive reactivity addition indicates a move toward supercriticality (power increase). A negative reactivity addition indicates a move toward subcriticality (power decrease).

Safety function This term applies to systems, structures, components, procedures, and controls (of a facility or process) that are relied upon to remain functional during and following design basis events. Their functionality ensures that key regulatory criteria, such as levels of radioactivity released, are met. Examples of safety-related functions include shutting down a nuclear reactor and maintaining it in a safe shutdown condition.

Seismic Category I Structures, systems, and components that are designed and built to withstand the maximum potential earthquake stresses for the particular region where a nuclear plant is sited.

Seismic Category II Nonsafety-related piping and components that support accident recovery functions.

Standby Liquid Control System (SLC) Provides an alternate method of reactor shutdown (i.e., without control rods) from full power to cold subcritical by the injection of a neutron absorbing solution into the Reactor Pressure Vessel for a BWR. A SLC system would have redundant and independent 50% capacity trains, which include piping, valves, accumulator and instrumentation that can inject a neutron absorber solution into the reactor. The system is designed to operate over the range of reactor pressure to inject sufficient neutron absorber solution to reach hot subcritical conditions after system initiation.

Turbine Component Cooling Water System (TCCWS) Provides cooling water to all turbine island auxiliary equipment to provide a continuous supply of cooling water to the turbine island auxiliary equipment. The TCCWS is designed to permit the maintenance of any single active component without interruption of the cooling function. Heat is removed from the TCCWS and transferred to the Nonsafety- Related PSWS.

Introduction

Balance of plant systems consist of the remaining systems, components, and structures that comprise a complete nuclear power plant and are not included in the nuclear steam supply systems as defined under 10 CFR 170.3 Definitions for nuclear plants licensed in the US or equal for international design. LWR NSSS are described for PWR in (Brown, 2021) and BWR (Hamon, 2021).

These systems utilized in nuclear power plants include Fuel Storage and Handling Systems, FAPCS, RCCWS, PSWS, DCS, Control Room Habitability HVAC systems and Radiation Monitoring systems.

There are numerous nuclear island and non-nuclear island auxiliary systems, such as instrument and service air, condensate/feedwater and demineralized water transfer, chilled water, TCCWSs, HVAC, equipment drain, floor drain, fuel handling and cranes, makeup water systems, potable water and sanitary waste systems, sampling systems, SLC, auxiliary boiler steam supply, water chemistry systems, communications, lighting, standby electrical power systems, fire protection and other systems which are similar between LWR technology BWR and PWR plants and are not covered here, since the designs are essentially the same as non-nuclear counterparts, and for space reasons, are not further described in this article.

Balance of plant systems are separate from power generation systems of nuclear plants that include main/extraction steam, feedwater and condensate systems, chemical addition system, condensate makeup purification system, auxiliary steam system and passive plant PWR backup feedwater system.

Balance of plant system designs utilized at nuclear plants have similarities between current BWR and PWR designs, ALWR plants, Small Modular LWR (smLWR) and evolutionary plants. The similarities lead to designs which incorporate numerous common requirements.

Balance of Plant systems may support safety-related or nonsafety-related functions based on the design of the plant. Safety-related applies to systems, structures, components, procedures, and controls (of a facility or process) that are relied upon to remain functional during and following design basis events. Their functionality ensures that key criteria, such as levels of radioactivity released, are met. Examples of safety-related functions include shutting down a nuclear reactor and maintaining it in a safe shutdown condition. Advanced and evolutionary nuclear plants are being designed to minimize safety-related functions fulfilled by balance of plant systems.

Fuel storage and handling

Nuclear reactor plants include facilities for the storage of new and spent fuel assemblies. The safety functions of the new fuel storage vault, new fuel storage racks, spent fuel pool, and spent fuel storage racks are to maintain the fuel assemblies in a safe and subcritical array during all credible storage conditions and to provide a safe means of loading the spent fuel assemblies into shipping or storage casks.

Nuclear reactor plants include facilities for storage of new and spent fuel. The new fuel storage facility includes the fuel assembly storage racks, the concrete storage vault that contains the storage racks, and the auxiliary components. The spent fuel storage facility includes the spent fuel storage racks, the spent fuel storage pool that contains the storage racks, and the associated equipment storage pits.

For BWRs, upon receipt of the new fuel bundles at the reactor site, each fuel bundle container is normally uncrated from its shipping crate and the fuel bundle container moved to the refueling floor. The fuel bundles are removed from the container and moved to a new fuel inspection stand where the fuel bundles are inspected and the fuel channels are installed to create fuel assemblies. For PWRs, the fuel assemblies are generally removed from the shipping container, into the fuel inspection stand, and then directly to designated new fuel storage or directly to the spent fuel pool.

The fuel assemblies would then be placed in the spent fuel pool until time to move them into the reactor. The fuel assemblies are normally stored in underwater storage racks. The racks are accessed using a refueling machine.

Spent fuel immediately removed from the reactor vessel must be stored underwater for decay heat removal. Spent fuel racks are used for long-term storage of spent fuel. These spent fuel storage racks are located at the bottom of the storage pools at a depth sufficient to provide adequate radiological shielding.

Another aspect of spent fuel storage is dry fuel storage. Nuclear plants typically reserve space within the site security fence for dry fuel storage. The area reserved shall be sufficiently large to accommodate a storage facility with a capacity for storage of spent fuel elements for up to a 60-year period of plant operation. Because of the potential for extension to an 80-year period of plant operation, consideration is given for reserving an area for a dry fuel storage facility with a capacity for storage of spent fuel elements for an 80-year period of plant operation.

The spent fuel storage pool water is processed by a FAPCS, which provides cooling to the spent fuel and maintains the spent fuel storage pool water quality.

New fuel storage

New fuel storage racks contain storage space for new fuel assemblies.

Nuclear design basis

The new fuel storage racks are designed to assure that the fully loaded array is subcritical by a predetermined margin.

The biases between the calculated results, experimental results, and the uncertainty in the calculation, are taken into account as part of the calculation procedure to assure that the specific limit is met.

Material considerations

Material used in the fabrication of the new fuel storage racks is normally limited to the use of stainless steel in accordance with the latest issue of the applicable American Society for Testing and Materials (ASTM) specifications at the time of equipment order.

Safety evaluation

Criticality control

The design of the new fuel storage racks provides for **reactivity** limits for storage conditions. To ensure that design criteria are met, the following normal and abnormal new fuel storage conditions are normally analyzed:

- Racks are loaded with fuel of the maximum fuel assembly **reactivity**;
- Normal positioning in the new fuel array; and
- Eccentric positioning in the new fuel array.

New fuel storage racks criticality control meets the requirements of 10 CFR Part 50.68(b) for nuclear plants licensed in the US or equal for international design.

Structural design

The new fuel storage racks are designed to meet **Seismic Category I** requirements. Stresses in a fully loaded rack do not exceed stresses specified by the applicable American Society of Mechanical Engineers (ASME) Codes and Standards when subjected to seismic loads.

The storage rack structure is designed to withstand the impact resulting from falling fuel assemblies and the fuel grapple, which is the portion of the fuel handling machine that interfaces with the fuel assembly handle.

Procedural fuel handling requirements and equipment design limit the number of assemblies that can be handled over the storage racks at any one time, typically only one. The structural arrangement is such that no lateral displacement of the fuel occurs; therefore, subcritical spacing is maintained. An irradiated fuel assembly is not to be placed in a rack specifically designated as new fuel storage.

The racks are fabricated from material specified to ASTM or equivalent international standards.

Protection features of the new fuel storage facilities

The new fuel storage racks are housed in a **Seismic Category I** structure designed for natural phenomena such as tornadoes, tornado missiles, floods and high winds.

A refueling machine is used to move fuel. It contains interlocks to prevent overloads from being applied to the bail of the fuel assembly. Thus, the transfer devices used for new fuel handling to the new fuel rack cannot impose excessive uplift loads on the rack.

Should it become necessary to move major loads along or over the pools, administrative controls require that the load be moved over the empty portion of the pool and avoid the area of the new fuel racks. Procedures are written for fuel handling.

Spent fuel storage

Additional details associated with nuclear spent fuel storage are provided in for more details see ([Glatz, 2021](#)) and ([Kessler, 2021](#)).

Design bases

On-site storage is provided in the spent fuel pool for unconsolidated spent fuel assemblies resulting from a minimum of 5 years of plant operation plus the total number of assemblies in one core (typical loading) (NUREG-0800 Standard Review Plan-9.1.2; US Nuclear Regulatory Commission, Revision 4—March [2007](#)). In addition to this fuel storage, space shall also be provided in the pool for storage of control elements, fuel channels, equipment for inspecting fuel and channels and leak testing equipment ([Young, 2021](#)).

Nuclear design basis

New and spent fuel storage racks are capable of maintaining fuel subcritical. A full array in the loaded spent fuel rack is designed to be subcritical by a predetermined margin. Neutron absorbing material (ex. borated stainless steel in accordance with ASTM A-887 ([ASTM, 2020](#))), as an integral part of the design, is normally employed to assure that the calculated **reactivity** coefficient including biases and uncertainties, does not exceed the limit under all normal and abnormal conditions.

The biases between the calculated results and experimental results, as well as the uncertainty involved in the calculations, are taken into account as part of the calculative procedure to assure that the specific **reactivity** coefficient limit is met.

Criticality control

The spent fuel storage racks are designed to assure that the fully loaded array is subcritical by a predetermined margin.

Because of the complexity of the configuration, Monte Carlo neutron transport techniques are employed in the calculations performed to assure that the **reactivity** of the worst case configuration does not exceed the predetermined margin of subcriticality under all normal and abnormal conditions, including consideration for the exposure-dependent **reactivity** of the fuel assemblies.

The biases between the calculated results, experimental results, and the uncertainty in the calculation, are taken into account as part of the calculative procedure to assure that the specific k_{eff} limit is met. Spent fuel storage racks criticality control meets the requirements of 10 CFR Part 50.68(b) for nuclear plants licensed in the US or equal for international design.

Structural design and material compatibility requirements

The spent fuel pool is normally a reinforced concrete structures with a stainless steel liner. Fuel storage racks and pool liners are designed to meet **Seismic Category I** requirements. Pool liner and anchorage are designed to the same loads and load combinations as the pool concrete structure except that load factors for all cases are equal to 1.0, and the acceptance criteria follow ASME Section III, Division 2, CC-3700 (ASME, 2019). Pool liners are evaluated to ensure structural integrity under fuel handling accidents.

The fuel racks support axially the weight of the fuel assembly or bundle. Individual racks are spaced less than one fuel assembly apart so that a fuel assembly cannot be inserted between racks. In the event that a fuel assembly is lowered adjacent to an exterior rack, this configuration is analyzed.

The support structure allows sufficient pool water flow for natural convection cooling of the stored fuel and allows the rack material temperatures to stay within limits.

Following the Fukushima-Daiichi accident, advanced and evolutionary nuclear plants are designing spent fuel pools with sufficient pool volume adequate to accommodate a loss of normal pool decay heat removal for a period of time (typically 72 h) without a need for additional makeup while satisfying the shielding requirements for the fuel. The spent fuel pool cooling system will be analyzed to ensure that for all postulated accidents, the site boundary dose will be below regulatory limits.

The racks are fabricated from materials specified in accordance with the latest issue of applicable ASTM specifications, or international equivalent, at the time of equipment order.

The racks are designed to withstand the impact force generated by the vertical free-fall drop of a fuel assembly and its handling tool from the maximum height expected during normal fuel handling.

The rack is designed to withstand a pull-up force in the event a fuel assembly is stuck.

The fuel storage pools are designed to have adequate water shielding for protection against the neutron and photon radioactivity emitted from the stored spent fuel. The depth is such that even when fuel assemblies are raised above the storage racks containing other fuel, there is adequate depth of water to provide this shielding.

The structures which contain the fuel storage equipment, including the storage racks and pool, are designed to protect the fuel from damage caused by:

- Natural events such as earthquake, high winds and flooding; and
- Mechanical damage caused by dropping of fuel assemblies, bundles, or other objects onto stored fuel.

Summary of radiological considerations

By adequate design and careful operational procedures, the design bases of the spent fuel storage arrangement are satisfied. Thus, the exposure of plant personnel to radiation is maintained well below regulatory limits and in accordance with ALARA principles.

Fuel and auxiliary pools cooling system (FAPCS)

Nuclear reactor plants include a spent fuel pool for the storage of spent fuel assemblies. The methods used to provide cooling for the removal of decay heat from the stored assemblies vary from plant to plant, depending upon the individual design. The safety function to be performed by the system in all cases remains the same; that is, the spent fuel assemblies must be cooled and must remain covered with water during all storage conditions. Other functions performed by the system but not related to nuclear safety include water cleanup for the spent fuel pool, refueling canal, refueling water storage tank, and other equipment storage pools; means for filling and draining the refueling canal and other storage pools; and surface skimming to provide clear water in the storage pool.

A second function of the FAPCS is to maintain visual clarity and purity of the spent fuel pool cooling, safety pool (passive plants), and refueling cavity fill water. The typical system consists of independent subsystems, each with pumps, piping, a heat exchanger, filter and demineralizer capacity and associated equipment and controls for regulating the system flow. Typically, only the cooling function is safety-related for evolutionary plants. Both the cooling and maintenance of clarity functions are non-safety-related for passive plants.

Legacy spent fuel pool cooling systems utilized at PWR and BWR nuclear plants utilize active cooling systems requiring (Alternating Current) (AC) power. Power is supplied from either on-site or offsite sources. The cooling system consists of appropriately redundant equipment so that a single active component failure will not result in a loss of normal cooling. Passive FAPCS have been specified for advanced and evolutionary nuclear designs that do not include the provision for safety-related AC power. In addition,

the spent fuel storage pool will be designed with a pool volume adequate to accommodate a loss of normal fuel pool decay heat removal for a period of time (usually 72 h) without the need for AC power while satisfying the shielding requirements of the fuel.

Power generation design basis

FAPCS provides continuous cooling and cleaning of the spent fuel storage pool during normal plant operation. It also provides occasional cooling and cleaning of various pools located inside the containment during normal plant operation and refueling outages.

System description summary

The FAPCS consists of physically separated cooling and cleanup trains. Redundancy and physical separation are provided for active components in lines dedicated for supporting pool cooling functions. Each train typically contains a pump, a heat exchanger and a water treatment unit for cooling and cleanup of various cooling and storage pools. The FAPCS includes high point vents and component vents necessary to avoid gas accumulation.

The primary design function of FAPCS is to cool and clean pools located in the containment and nuclear island structures during normal plant operation. FAPCS provides flow paths for filling and makeup of these pools during normal plant operation and during post-accident conditions, as necessary.

Instruments are made for indication of operating conditions to aid the operator during the initiation and control of system operation. Provisions are provided to prevent inadvertent draining of the pools during FAPCS operation by including anti-siphon holes on FAPCS piping that is normally submerged.

The FAPCS is designed to provide for the collection, monitoring, and drainage of pool liner leaks from the spent fuel pools and auxiliary pools to the Liquid Waste Management System.

The FAPCS piping and components that are required to support safety-related or accident recovery function have Seismic I or II classification. A Seismic I classification is required for all safety-related functions. The remaining nonsafety-related piping and components that support accident recovery functions are **Seismic Category II**.

System operation

FAPCS cooling and cleanup trains operate continuously to cool and clean the water in the spent fuel pool during normal plant operation and refueling outages. Operation of only one FAPCS cooling and cleanup train of redundant train designs is sufficient to handle the cooling requirements under the normal heat load condition in the spent fuel pool. Operation with up to two FAPCS cooling and cleanup trains is sufficient to handle the cooling requirement under the maximum heat load condition. At least one FAPCS cooling and cleanup train is available for cooling the spent fuel pool, except for a short period as long as the water temperature in the pool remains below the maximum temperature limit for normal operation.

During a refueling outage, FAPCS can be operated in the Fuel and Auxiliary Pool Cooling and Cleanup mode with both cooling and cleanup trains under the maximum heat load condition in the spent fuel pool.

Plant service water system (PSWS)

The PSWS provides essential cooling to safety-related equipment and may also cool nonsafety-related auxiliary components used for normal plant operation. The ultimate heat sink is the intake source of water to the PSW for long-term cooling of station features required for plant shutdown and also of any special equipment required to prevent or mitigate the consequences of postulated accidents and as such is an PSW interface system. The ultimate heat sink and plant cooling water system designs are required to operate under extreme environmental conditions such as extremes in ambient temperatures and drought conditions. Systems utilizing water conservation measures are applied to advanced and evolutionary nuclear plant designs.

BWR and PWR plants have many similarities in their cooling water systems. The similarities lead to designs which incorporate numerous common requirements, i.e., the basic systems utilize the same types of pumps, heat exchangers and piping assembled into similar system configurations.

Power generation design bases

The PSWS provides the required cooling to the RCCWS and TCCWS heat exchangers.

The PSWS is typically designed so that neither a single active nor single passive component failure results in a complete loss of nuclear island cooling and/or plant dependence on any safety-related system. This is achieved by redundant components, automatic valves and piping cross-connects for increased reliability.

The PSWS is designed for ease of restoration of its function after a component failure without plant operating mode or power level change.

The PSWS is designed to operate during a Loss of Preferred Power (LOPP). Typically, independent on-site power supplies are specified to provide a high availability of electric power to the PSWS.

The PSWS is designed for remote operation from the main control room.

Summary description

The PSWS rejects heat from RCCWS and TCCWS heat exchangers to the environment. The source of cooling water to the PSWS is site specific with the heat rejection facilities dependent on actual site conditions.

Operation

The PSWS operates during startup, normal power operation, hot standby, cooldown, shutdown/refueling, and LOPP.

Operation of individual redundant PSWS pumps is sufficient for the design heat load removal in any normal operating mode. During normal and LOPP cooldown mode sufficient redundancy is provided in system design to provide for operational convenience to bring the plant to cold shutdown condition in limited time (normally 24 h).

During a LOPP, the running PSWS pumps restart automatically using power supplied by the nonsafety-related standby diesel-generators.

Reactor component cooling water system (RCCWS)

Service water shall not be used directly for equipment cooling due to the issues of fouling and corrosion caused by raw service water. Therefore, water from the closed loop component cooling water system shall be utilized to provide a barrier between contaminated and raw water systems and reactor component heat loads.

The RCCWS provides a closed loop of cooling water for reactor system components, reactor shutdown equipment, ventilation equipment, and components of the ECCS required for safe shutdown during normal operations, anticipated operational occurrences, and accident conditions and for prevention or mitigation of the consequences of accidents.

Service water also supplies the Turbine Building Closed Cooling Water System that typically cools chillers, turbine lube oil coolers, feedwater pumps, condensate pump motors, booster pump motors, main generator cooling and air compressor cooling loads.

Power generation design bases

The RCCWS provides cooling water to plant auxiliary equipment during startup, normal power operation, hot standby, and plant cooldown. The RCCWS is also designed to operate during a LOPP.

The RCCWS is designed so that neither a single active nor credible single passive component failure results in a complete loss of active nuclear island cooling and/or plant dependence on any safety-related system. Typically, this requirement is addressed through redundant trains of RCCWS.

The RCCWS is designed for ease of restoration after a single component failure without plant operating mode or power level change. Typically, this requirement is addressed through redundant trains of RCCWS or multiple components arranged in parallel. The RCCWS is designed to limit leakage of radioactive or chemical contamination to the environment. Typically, this is accomplished by heat exchanger design that is not susceptible to cross contamination (ex. Plate heat exchanger) and design of leak detection methods to preclude unmonitored release of radioactive liquids to the environment.

Summary description

The RCCWS provides cooling water to components in the nuclear island and provides a barrier against radioactive contamination of the PSWS.

The RCCWS operates during startup, normal power operation, hot standby, normal cooldown, shutdown/refueling, and LOPP.

RCCWS heat exchanger operation is coordinated with PSWS flow. RCCWS cooling water flow through a RCCWS heat exchanger is only allowed if there is a corresponding PSWS water flow to absorb the heat load.

Control room area ventilation system (CRAVS)

HVAC systems utilized for ventilation and cooling functions at nuclear plants provide a suitable environment ensuring the safety and comfort of plant personnel and operability of plant equipment during normal operating conditions (passive and evolutionary plants) and postulated DBA conditions (evolutionary plants).

The CRAVS provides a controlled environment for the comfort and safety of control room personnel and assures the operability of control room components during normal operating, anticipated operational transient, and DBA conditions. Portions of the CRAVS also may be relied upon to ensure coping with and recovering from a station blackout event.

For accident conditions where the CRAVS is available, the system shall be designed to transfer from its normal operating mode either to its isolation/recirculation mode upon detection of conditions that could result in induction of airborne hazardous chemicals or smoke in the control room, or to its pressurization mode (through the supplementary filter unit) to mitigate accidental exposure of control room personnel to a high level of airborne radioactivity.

The control room ventilation system and control building layout and structures ensure that plant operators are adequately protected against the effects of accidental releases of toxic and radioactive gasses and to assure conformance with the requirements of specific design criteria and regulations.

The CRAVS maintains space design temperatures, quality of air and pressurization. It provides a controlled environment for personnel safety and comfort, and for the proper operation and integrity of equipment.

- The CRAVS will meet the acceptance criteria of General Design Criteria 5, Sharing of Structures, Systems, and Components (Appendix A to Part 50—General Design Criteria for Nuclear Power Plants, 2021) for sharing of structures, systems, and components for sites with multiple reactors:
 - Each unit at a multi-unit site has a separate control room;
 - An accident in one unit does not impair the ability to perform safety functions of the remaining units; and
 - An orderly shutdown and cooldown of remaining unit(s) would not be impaired.
- The CRAVS meets the acceptance criteria of General Design Criteria 19, Control Room (Appendix A to Part 50—General Design Criteria for Nuclear Power Plants, 2021) for the control room. The control room ventilation is isolated on loss of normal AC power or if high radioactivity is detected with a safety-related system automatically initiated to pressurize and provide radiologically filtered air to the control room area. Radiation detectors in the intake air supply provide warning and initiate actions to protect control room personnel under accident conditions. This safety related ventilation system design maintains a habitable control room under accident conditions by providing adequate radiation protection and breathing air.
- The CRAVS meets the acceptance criteria of General Design Criteria 60 (Appendix A to Part 50—General Design Criteria for Nuclear Power Plants, 2021) for control of releases of radioactive materials to the environment. The CRAVS meet the guidance of RG 1.52 as related to design, testing and maintenance criteria for atmosphere cleanup system and normal ventilation system air filtration and adsorption units.

Advanced and evolutionary nuclear plants have applied passive means to meet control room habitability requirements including pressure integrity and temperature control. For accident conditions if the main control room HVAC system is not operational (e.g., if AC power is not available), a safety grade main control room pressurization system shall provide a positive air pressure in the control room so that the main control room can be maintained as the primary location from which technical personnel can safely operate. The main control room can also be designed with the capability to provide suitable temperature conditions for room heat loads generated in the control room during loss of AC power events during the duration of the AC loss of power event (normally assumed for 72 h).

Safety design bases

The CRAVS provides the following safety-related design basis functions:

- Monitors the control room area air supply for radioactive particulate and/or iodine concentrations; and
- Isolates the normal CRAVS air supply, starts an ESF fan, and aligns the air supply through the safety-related filter unit, upon a high radiation detection signal in the control room area normal air supply, or upon an extended loss of AC power.

The portions of the CRAVS which penetrate the control room area habitability envelope are safety-related and designed as **Seismic Category I** to provide isolation of the space from the outside and surrounding areas in the event of a DBA. The ESF portion of the CRAVS subsystem is safety-related and designed and supported as **Seismic Category I** including the air intakes, ductwork, dampers, fans, instrumentation and controls. The remaining CRAVS functions are nonsafety-related. The penetrations contain safety-related isolation dampers or valves that fail closed upon a loss of control signal, power, or instrument air. An ESF unit is automatically actuated upon radiological isolation of the control room area habitability envelope or an extended loss of AC power. If the initial ESF unit fails to start or is otherwise unavailable, the second standby ESF unit automatically actuates.

CRAVS equipment and ductwork whose failure could affect the operability of safety-related systems or components are designed as **Seismic Category II**. The remaining portion of the system is nonsafety-related and nonseismic.

Power generation design bases

The CRAVS:

- Provides a controlled environment for personnel comfort and safety. Sufficient outside air is provided to meet the ventilation requirements for acceptable indoor air quality as defined under ASHRAE 62.1, Ventilation for Acceptable Indoor Air Quality (62.1, Ventilation For Acceptable Indoor Air Quality, 2019);
- Provides a controlled environment for the proper operation and integrity of equipment in the control room area during normal, startup and shutdown operations;

- Provides redundant active components to increase reliability, availability and maintainability of the ventilation system;
- Provides shutoff dampers on the inlet and outlet of fans and **Air Handling Units (AHUs)** if necessary to allow for maintenance;
- Provides shutoff valves at the inlet and outlet of cooling coils if necessary to allow for maintenance;
- Provides access for AHU fans, filter sections and duct mounted dampers to allow for maintenance;
- Provides the capability for manual control of system fans to facilitate maintenance and testing;
- Minimizes exposure to personnel during inspection and maintenance by locating equipment and instrumentation as far as practical from potential sources of high radiation;
- Maintains higher than atmospheric (positive) pressure to minimize the infiltration of outside air. Construction materials and processes that ensure the control building structure maintains low leakage or leak tight conditions above and below grade. The CRAVS envelope penetrations are sealed and access doors are designed with self-closing devices that close and latch the doors following use. Normally, there are double door airlocks in the control room area habitability envelope for access and egress during emergencies when the CRAVS is isolated and an ESF unit is operating;
- Reduces the potential spread of airborne contamination by maintaining airflow from areas of lower potential for contamination to areas of greater potential for contamination. The CRAVS is maintained at a higher pressure than surrounding areas except during the isolation and smoke exhaust modes;
- Detects and limits the introduction of airborne hazardous materials (radioactivity or smoke) into the control room habitability area;
- Provides the capability to exhaust smoke, heat and gaseous combustion products from inside the control room area to the outside atmosphere in the event of a fire. Construction materials and processes ensure that materials of construction are non-combustible and heat and flame resistant wherever possible. Materials that produce toxic or noxious vapors when subjected to a fire are avoided;
- Smoke control and removal functions are in accordance with National Fire Protection Association guidelines;
- Is designed such that failure of nonsafety-related equipment does not compromise or otherwise damage safety-related equipment; and
- Is provided with bullet-resistant exterior HVAC openings that penetrate the control room vital envelope in accordance with 10 CFR 73 (10 CFR 73, Physical Protection of Plants and Materials, 2021b).

Drywell and containment cooling system

The drywell (BWR) or containment cooling (PWR) systems provide the functions of an auxiliary and radwaste area ventilation system to maintain ventilation, permit personnel access, and control the concentration of airborne radioactive material in the auxiliary and radwaste equipment areas of a nuclear plant during normal operation and anticipated operational occurrences, and after postulated accidents.

The containment design for a BWR or PWR includes a drywell cooling or containment cooling system to maintain temperatures during normal operation within acceptable limits for equipment operation. Additional details associated with BWR and PWR containments is contained in [Sharpe \(2021\)](#).

Safety design bases

The drywell or containment cooling system has no safety-related function, and thus, has no safety design basis. The drywell or containment cooling system shall be designed as a nonsafety, nonseismic system powered from the permanent nonsafety distribution system. A separate safety-related system to remove heat from the reactor containment under DBA conditions is also provided. Advanced and evolutionary reactor designs employ passive heat removal systems to fulfill this function.

Power generation design bases

The drywell or containment cooling system performs the following functions during stable and transient operating conditions through the entire operating range, from startup to full load condition to refueling:

- Maintain temperature in the drywell/containment spaces within specified limits during normal operation;
- Accelerate drywell/containment cooldown following a LOPP during the period from hot shutdown to cold shutdown;
- Aid in complete purging of nitrogen from the drywell (BWR) during shutdown;
- Maintain a habitable environment for plant personnel during plant shutdowns for refueling and maintenance.
- Limit drywell/containment temperature during LOPP.

Summary description

The drywell or containment cooling system maintains the thermal environment within the drywell/containment to specified conditions during normal reactor operation, hot standby and refueling using Fan Cooling Units (FCUs) typically.

The drywell or containment cooling system is a closed loop recirculating air/nitrogen cooling system with no outside air/nitrogen introduced into the system except during refueling. The system uses direct drive-type FCUs to deliver cooled air/nitrogen to various areas of the upper and the lower drywell/containment. Ducts distribute the cooled, recirculated air/nitrogen through diffusers and nozzles. The drywell heat loads are transferred to the cooling medium circulating through the cooling coils of the FCUs.

The cooling medium of the FCUs is chilled water or reactor component cooling water. There are typically separate FCUs for the upper and the lower drywell/containment regions to optimize space cooling.

PWR and BWR containment design differences lead to differences in drywell cooling and containment cooling system design:

- BWR drywell volumes are typically smaller than PWR containment structures requiring an inserted nitrogen atmosphere for combustion gas control under an accident. This requires the DCS to operate in a nitrogen environment compared to an air atmosphere for the PWR,
- PWR containment design pressures and allowable leakage rates are typically greater than those allowed in BWR designs.

Radiation monitoring system

Criteria exist in 10 CFR 50 that require the control, monitoring, and radiological evaluations of all releases, documentation and reporting of all radiological effluents discharged into the environment. The NRC requires power reactor licensees apply ALARA principles to radioactive effluents for the protection of the public. The ALARA criteria contained in Appendix I of 10 CFR Part 50 are:

“The licensee shall establish an appropriate surveillance and monitoring program to:

1. Provide data on quantities of radioactive material released in liquid and gaseous effluents...;
2. Provide data on measurable levels of radiation and radioactive materials in the environment to evaluate the relationship between quantities of radioactive material released in effluents and resultant radiation doses to individuals from principal pathways of exposure; and
3. Identify changes in the use of unrestricted areas (e.g., for agricultural purposes) to permit modifications in monitoring programs for evaluating doses to individuals from principal pathways of exposure.”

To meet these requirements, nuclear plants employ radiation monitoring systems of two basic types: process radiation monitoring and area radiation monitoring. With the former, certain plant processes are monitored in order to detect radioactivity in excess of acceptable limits. These vary somewhat, depending on the type of reactor in which they are employed, because the processes vary between those reactor types. For instance, in BWRs, the main steam line is monitored in the steam tunnel in order that gross fuel failures may be detected. High radiation levels may initiate a reactor trip. The detectors are generally ionization chambers, sensitive to gamma radiation, and are linked to the reactor protection system. Additional monitoring is performed on the offgas treatment system, the offgas vent pipe, the liquid radioactive waste treatment system and the containment ventilation discharge. Limits are set so as to protect against releases to the environment exceeding those determined to be acceptable during plant licensing.

An example of a processing radiation monitoring application for a PWR is the steam generator blowdown sample monitor which typically monitors the liquid phase of the steam generators for radioactivity indicative of a primary-to-secondary system leak. The detectors are gamma scintillation detectors, mounted in liquid samplers surrounded by lead shielding.

The second form of radiation monitoring is area monitoring. For this, gamma-sensitive detectors, with several sensitivity ranges to match expected radiation levels, are distributed throughout the plant. The data are fed back to recorders in the control room. Levels are also indicated locally, and will have audible indication of exceeding allowable limits, for areas that are frequently occupied. These area monitors are intended to protect plant personnel.

Reactor safety principles

Although nuclear energy is very safe compared to other forms of electricity generation, with an excellent operational record approximately 1/1000 of casualty rates per terawatt-hour generated from fossil fuel (Ritchie, 2020), several reactor accidents have progressed beyond the design basis, becoming high-profile severe accidents. These events have had significant effects both from actual consequences and also from impact on the public perception of nuclear energy. In particular, Three Mile Island in Pennsylvania, Chernobyl in the former Soviet Union, and Fukushima Daiichi in Japan, have had a negative impact on the public perception of nuclear energy. See Skillman and Rempe (2021), Sich (2021), and Mizokami and Rempe (2021), respectively, for more complete discussions of these accidents. These major accidents were preceded by other historic events, like the partial meltdown at Fermi-1 in Michigan. Fermi-1 was widely chronicled in the 1975 Readers Digest book “We Almost Lost Detroit.” Later, the rebuttal, “We Did Not Almost Lose Detroit” noted the utility stressed that the incident at Fermi-1 was well within the plant’s safety envelope, even though it was built at a time when the regulator in the United States was not independent. Additionally, the accident was due to the last-minute addition of a component meant to enhance safety. This was an early example of how accidents, even without significant consequences to the public, can have a significant impact on public perception.

Safe reactor operation, as well as the culture of safety within all aspects of the nuclear fuel cycle from mining to final disposition, is key to the successful application of fission energy. The definition of reactor safety has evolved over the years. Historically, the first “critical piles” were operated in an ad hoc manner, with relatively few safety procedures. For example, the safety protocols at the US Army-operated Stationary Low Power Reactor 1 (SL-1) were only a few pages long. This reactor was the site of the deadliest nuclear accident resulting in the first immediate fatalities from nuclear energy in the United States. A maintenance crew of the reactor operator, the shift supervisor, and a trainee passed away due to the sudden steam explosion caused by a reactivity accident. The fuel ultimately melted down, as well, though this aspect of the accident did not cause additional casualties. This was all initiated by an error made by operational personnel. Similar errors contributed to other events, like the partial fuel meltdown at the 105 KW reactor (Sturges et al., 1955) in Washington state or the fire at Windscale in the United Kingdom, as detailed in Rempe (2021b).

These early life-and-death incidents helped transform the safety culture of the overall nuclear power enterprise to become more rigorous and proactive. For example, Admiral Hyman Rickover had developed a more rigorous safety culture within Navy program in contrast with the Army-operated SL-1. Similarly, the Three Mile Island accident revealed the concomitant risk of small equipment failures and human factors that can result in severe accidents, and thus emphasized the importance of operator training, emergency planning, plant operating histories, and other matters. More recently, the Fukushima Daiichi accidents have further emphasized the role of human factors in the emergency, even for the reactor designs that were safe, and emphasized the importance of *passive, sometimes also called inherent, safety* in reactor and reactor system design. The value proposition of inherent safety was demonstrated by the success of the sodium-cooled Experimental Breeder Reactor II (EBR-II) shutdown heat removal tests (SHRT) (McFarlane, 2021). These rigorous series of tests were instrumental in showcasing the potential for a particular reactor concept to be inherently safe in the postulated scenarios that were tested.

In general, testing and validation regimes are a vital part of reactor safety. A validation hierarchy exists where separate effects tests are used to understand phenomena and validate individual models, integral effects tests support multi-physics understanding, and engineering demonstration tests where these principles are demonstrated in an actual reactor. Analysis methods validated with actual data, along with an independent regulator and associated regulatory oversight, are key tenets of the modern reactor safety philosophy.

A key objective of reactor safety is to ensure there is no unacceptable release of fission products or other radioactive elements to plant personnel and especially to the public during all anticipated operational occurrences (AOOs) or design basis (postulated) accidents (DBAs) (IAEA, 2006), as discussed in Rempe (2021a). The key in AOOs is to ensure that there is no fuel damage and survives the event to generate energy in the future. The reactor safety objective in a DBA is to maintain a coolable geometry and avoid the release of any radioactive elements. If an AOO, DBA, or other event progresses outside of the design basis, to a beyond design basis accident (BDBA), the objective of reactor safety is to contain and limit any release of radioactivity to personnel within the *site boundary* and especially to the public beyond the site boundary.

Most AOOs or DBAs are mainly a problem of mitigating power-cooling mismatches due to overpower, under-cooling, or both. There are seven categories of events typically considered:

1. Increase in heat removal by the secondary system
2. Decrease in heat removal by the secondary system

3. Decrease in reactor coolant system flow rate
4. Reactivity and power distribution anomalies
5. Increase in reactor coolant inventory
6. Decrease in reactor coolant inventory
7. Radioactive release from a subsystem or component

Licensing for Nuclear Power Plants (NPP) requires a safety analysis report under 10 CFR 50 (U.S. NRC, 2011), that analyzes the design and performance of structures, systems, and components that have a safety function, and their adequacy for the prevention and mitigation of the consequences of such events. For details, see Rempe and Williams (2021). NUREG-0800 (U.S. NRC, 1987) and other Regulatory Guides discuss a subset of the transient and accident events that are within the scope of DBAs of a NPP, and are considered acceptable for use in developing and assessing evaluation models (Gauntt, 2021) for conservative safety analysis of DBAs.

For a more reliable framework towards risk-informed regulation, the NRC has defined two surrogate variables, core damage frequency (CDF) and conditional containment failure probability (CCFP) that are quantitative measures of reactor safety in Regulatory Guides for the regulation and licensing of NPPs. These variables are used to benchmark reactor safety performance against two quantitative measures of short term and long-term risk, respectively:

1. The risk to an average individual in the vicinity of a nuclear power plant of prompt fatalities that might result from reactor accidents should not exceed one-tenth of 1 % (0.1%) of the sum of prompt fatality risks resulting from other accidents to which members of the U.S. population are generally exposed.
2. The risk to the population in the area near a nuclear power plant of cancer fatalities that might result from nuclear power plant operation should not exceed one-tenth of 1 % (0.1%) of the sum of cancer fatality risks resulting from other causes.

Performance issues are defined as risk significant if they lead to an increase in CDF that is greater than 10^{-4} reactors per year. Risk significant issues involving core damage which lead to large, rapid, and unmitigated releases of radioactivity have the potential to cause deaths within the general populace before they can be evacuated (U.S. NRC, 2002). This risk is relevant to the first quantitative measure. The second quantitative measure is related to the longer-term risk of cancer from radioactive releases from the reactor.

The key to attaining these objectives is the principle of *defense-in-depth* where several layers of defense in the system serve as a credited barrier to fission product release (IAEA, 2000). Typically for many of the existing nuclear power reactors, these layers consist of the fuel matrix itself, the cladding, the coolant pressure boundary (in a pressurized system) or the primary coolant boundary (in a low pressure system), and the containment (primary or secondary). This concept is shown as an example in Fig. 1. Various reactor concepts under development may use different layers of defense-in-depth or so-called functional containment. One example of a functional defense-in-depth layer is the integral coolant system layouts of small modular reactors (SMRs) which aim to strengthen the first and subsequent layers by incorporating inherent and passive safety features. Regulatory bodies have identified potential opportunities and challenges in the features and the application of defense-in-depth for SMRs

Fig. 1 A conventional defense-in-depth approach where the fuel matrix, cladding, coolant pressure boundary (or primary coolant boundary), and containment provide barriers to the release of radioactive fission products, actinides, and other transmutation products.

(IAEA, 2018). Another example of a defense-in-depth layer in an advanced reactor concept is the use of the SiC-layer in tristructural isotropic (TRISO) fuel within a modular high-temperature gas-cooled reactor (mHTGR), which acts as a very small pressure vessel to contain fission products (Helmreich, 2021; Gerczak, 2021).

Layers of defense-in-depth can be uncredited, in which case they help to prevent the release of radioactivity but are not considered in the safety case, or credited, in which case they are an essential component of the reactor licensing case. Typically, in power reactor licensing the Standard Review Plan (SRP), NUREG-0800 may be applied prescriptively and deterministically to evaluate the safety of a particular light water reactor with uranium fuel and zirconium-based cladding. In this example, NUREG-0800 is used to evaluate against safety criteria regulations in the U.S. code of federal regulations, 10 CFR 50, relating to power reactor safety. While the methods in NUREG-0800 are prescriptive, use of NUREG-0800 is not, in fact, mandatory. Multiple examples of compliance with 10 CFR 50 exist that do not, in fact, conform to the methods provided in NUREG-0800.

The non-power reactor SRP, NUREG-1537 (U.S. NRC, 1996), provides an alternative *performance-based* approach to defense-in-depth, where demonstration of safety performance is acceptable. A performance-based approach is useful when a particular reactor technology cannot rely on the historical precedent of many decades of operational experience, and instead needs to demonstrate its performance via operation. For example, mHTGR TRISO fuel performance requires statistically significant measurements of demonstrated reactor safety performance over the range of operational conditions, AOOs, and DBAs. More recently, the Regulatory Guide for non-LWRs (U.S. NRC, 2019) addressed *risk-informed and performance-based (RIPB)* approaches that appropriately account for risk significance in establishing technical and regulatory requirements while increasing effectiveness and efficiency.

Many risk significant events are by definition caused by a breach of the credited layers of defense-in-depth. For example, fuel cladding, the coolant pressure boundary, and the containment boundary are all barriers to fuel and fission product release in a typical light water reactor.

The design principles of reactor safety are important technical requirements in the design of safety-related systems. These design principles (IAEA, 1999) include proven technology, redundancy, diversity, physical separation, independency, fail safe, and interlock principles, as defined below.

- (i) Principle of proven technology: The functional performance and the safety of all systems and components should already be proven by commercial usage in other plant types or industrial fields. One example is the application of the ASME Boiler and Pressure Vessel Code (ASME Code) to nuclear power plant construction, providing requirements for manufacturer certification and quality assurance for the design, materials, manufacturing, inspection, testing, and operation of boilers and pressure vessels. If not, the usage of the system component should be tested following the guidelines from the regulation agency.
- (ii) Principle of redundancy: The design of engineered safety systems requires the extra provision of more than the minimum number of components for a specific safety function. Such redundant provisions allow a safety function to be satisfied when one or more items are unavailable, due to a variety of unspecified potential failure mechanisms or maintenance.
- (iii) Principle of diversity: The diversity of system requires more than two system components operating for the same objective but in different means. The diversity is achieved by the use of different physical means or different equipment made by different manufacturers. The purpose of diversity is to prevent the unavailability of systems caused by the Common Cause Failures (CCFs).
- (iv) Principle of physical separation: The system components operating for the same functions should be physically separated by locating them far from each other or having physical protections between them, to minimize the CCFs or other unavailability caused by external sources.
- (v) Principle of independence: Each safety-related component should provide a single specific function and avoid being used for more than one system, to reduce the uncertainties in the system and potential for CCFs.
- (vi) Principle of fail safe: The design of main components should inherently lead to the reactor system safety, even if the components fail to operate as intended.
- (vii) Principle of interlock: Some safety features should be locked to operate or stop only if certain specific conditions are satisfied.

Inherent safety features

Inherent safety features are the first level feature to ensure nuclear reactor safety during the abnormal operation of a NPP. The key concept of inherent safety features is to recover the nuclear reactor system from abnormal operation by inherent feedback of physical phenomena.

Feedback can be either prompt and inherent or delayed and inherent, depending on the event in question. Inherent safety doesn't require a specific system component, but is achieved by unique physical features of the system. Inherent feedback is based on an unavoidable and totally reliable physical phenomena (e.g. thermal expansion in fast reactors). Inherent feedback is prompt if it immediately follows the prompt fission energy deposition: in particular, if it is directly related to the temperature or physical dimensions of the nuclear fuel where fission fragments are generated. Inherent feedback that is delayed requires an additional physical phenomenon, such as heat transfer to the coolant.

The inherent safety features can be different among the types of nuclear reactors, while the representatives are Doppler broadening, moderator temperature coefficient of reactivity, and void coefficient of reactivity, in Light Water Reactors (LWRs). All three of

these are inherent feedback, with Doppler broadening being prompt feedback and moderator temperature or void coefficient being delayed feedback. All three of these coefficients contribute to the overall power coefficient of reactivity.

- (i) Doppler broadening (i.e. fuel temperature): As the increase of reactor power results in the increase of fuel temperature, it broadens the resonances in the neutron absorption cross section of fertile material (e.g. ^{238}U) due to the thermal motion of target nuclei in the nuclear fuel. The broadened resonances increase the parasitic neutron absorption probability and consequently results in prompt negative reactivity feedback.
- (ii) Moderator temperature coefficient of reactivity: As the temperature of moderator increases, its density decreases resulting in the reduction of neutron slowdown. In thermal reactors, the decrease of neutron slowdown increases the probability of parasitic neutron absorption in the resonances on ^{238}U and reduces the probability of fission in thermal neutron region, giving negative reactivity to the system. There is also a spectral impact of the change in water temperature on cross sections in the thermal energy range.
- (iii) Void coefficient of reactivity: As the increase of the moderator (water for LWRs) temperature leads to boiling, the voids (steam for LWRs) are produced inside the moderator. The formation of voids reduces the neutron slowdown by the moderator even more than due to moderator temperature increase resulting in even more negative reactivity feedback.

Among these example feedbacks, the fuel temperature coefficient is the main prompt feedback mechanism. Doppler broadening provides the shortest possible feedback loop. Doppler broadening occurs simultaneously with the deposition of kinetic energy from fission products. The Doppler coefficient is typically calculated as a temperature coefficient ($\partial\rho/\partial T$ in which ρ denotes reactivity). Moderator temperature and void coefficients of reactivity are examples of delayed feedback mechanisms, which are initiated by the heat transferred from the fuel to the coolant. Inherent safety features of some advanced reactor concepts are discussed in the last section.

Operational modes of NPPs

In general, normal operation of a NPP refers to the operation within the power operating range. However, there are also other operational modes in the category of normal operation. Each operational mode is defined as each combination of core reactivity condition, power level, and average reactor coolant temperature. For example, the operational modes of the Westinghouse Advanced Passive 1000 (AP 1000) plant include power operation, startup, hot standby, hot shutdown, cold shutdown, and refueling. However, the operational modes can differ for various NPP designs. Here, we briefly describe the representative operational modes of the existing PWRs as follows. More information on the reactor operation is discussed in [Young \(2020\)](#).

- (i) Power operation: A critical operation with a power over 5% of its full-power capacity is defined as power operation mode by NRC. During the power operation mode, a power cycle is established from a nuclear fuel where heat energy generated from nuclear fission reaction is transferred to a primary coolant, then to a heat sink where the energy is transferred to a secondary system for generation of electricity (e.g. a steam generator for a Pressurized Water Reactor [PWR]). The primary concern during the power operation is to keep the core critical. Typically, the reactivity control is achieved by using control rods and soluble poisons. The insertion or withdrawal of control rods is for the prompt reactivity control, while the long-term reactivity control is achieved by the soluble poisons (e.g. boron) in the primary coolant and the burnable poison rods. The entire systems including main control systems (e.g. reactor control system, feedwater control system, etc.) and auxiliary control systems (e.g. chemical and volume control system, etc.) are automatically controlled during the power operation mode in most of the operating NPPs.
- (ii) Startup: The startup of a NPP begins from a subcritical state and includes hot standby, hot shutdown, or cold shutdown states. When the nuclear reactor is shut down due to minor component or instruments malfunctions, and re-operates within a few hours, the startup of reactor is initiated from a hot standby state whose system conditions are close to those of power operation mode. Therefore, it takes a relatively short time, about an hour, to reach the full-power level after startup from hot standby. However, it takes longer, over 12 h, to reach the full-power level after the startup from cold shutdown in the case of refueling.
- (iii) Cooldown: Cooldown is a process leading the nuclear reactor from zero power state to cold shutdown state. The first step of cooldown is the heat removal from the primary system by the steam generator. The circulation of primary coolant is achieved by forced flow by pump or natural circulation inside the system. If the pressure and temperature of primary coolant fall below the limit, the heat removal of primary system is achieved only by the Residual Heat Removal System (RHRS). Usually, it takes a minimum of about a day for the temperature of primary coolant to reach that of the refueling condition. During the cooldown of reactor, the boron concentration inside the primary system is raised to compensate the positive reactivity feedback caused by the decrease of temperature.

Example reactor safety systems

The Plant Protection System (PPS) provides prevention and mitigation of reactor from exceeding safety limits during AOO or postulated accidents in the reactor. The PPS consists of Reactor Protection system (RPS) and Engineered Safety Features Actuation system (ESFAS).

- (i) Reactor protection: The RPS, also known as the reactor trip system (RTS), monitors system variables related to the reactor safety and automatically shuts down the reactor if one or more of those variables reach the certain point, referred to as the trip setpoint. The trip setpoints of RPS are set not to exceed the safety limits of the reactor system for AOOs. Example safety limits for a PWR typically include a local heat flux limit on the fuel surface (e.g. Critical Heat Flux Ratio or Departure from Nucleate Boiling Ratio), a limit on linear heat generation rate (i.e. Maximum Linear Heat Generation Rate, MLHGR), a limit on system pressure less than 110% of design value, and so on. The heat flux limit and linear heat generation rate limit are deterministically Specified Acceptable Fuel Design Limits (SAFDL) that should not be exceeded during any condition of normal operation including the effects of AOOs (U.S. NRC, 2011). For an advanced reactor with a performance-based approach the equivalent concept is the specified acceptable radionuclide release design limits (SARRDLs). For example, the safety case for TRISO fuel forms is typically performance-based and is focused on the definition of appropriate SARRDLs, as opposed to deterministic SAFDLs. Within the criteria of safety limits, Limiting Safety System Settings (LSSS) is set as a conservative limit to initiate the RPS during the design basis transients of reactor. Finally, for the commercial operation of NPP, one should follow the Limiting Conditions for Operation (LCO) defined by technical specification.
- (ii) Engineered safety feature actuation: When the reactor system variables approach the relevant safety setpoints, the ESFAS generates an actuation signal for an Engineered Safety Feature (ESF) (Lutz and Williamson, 2021) to mitigate the risk from the accidents below the acceptable criteria. Typical actuation signals generated by ESFAS for a PWR include a safety injection, containment isolation, containment spray, recirculation, and emergency actuation signals, and main steam isolation signal.

ESF refers to the safety systems necessary to prevent and mitigate the consequences of postulated accidents in the nuclear reactor. Typical ESFs for a PWR include core cooling system, containment system, residual heat removal system, emergency feedwater system, fission product removal and control system, habitability system, and so on. A detailed description of main ESFs for PWRs are described as follows:

- (i) Emergency core cooling: The Emergency Core Cooling System (ECCS) provides fuel cooling by supplying emergency coolant into the core during the Loss of Coolant Accident (LOCA). The main purpose of an ECCS is to keep the integrity of fuels by removing stored energy and decay heat in the core during LOCA, which mitigates progression to a severe accident. In a PWR, the ECCS consists of a High Pressure Safety Injection System (HPSIS), a Safety Injection Tank (SIT), and a Low Pressure Safety Injection System (LPSIS), which operate independently. The HPSIS provides emergency coolant into the core from a Refueling Water Storage Tank (RWST) using pumps with low flow and high head, while the LPSIS uses pumps with high flow and low head for enhanced operation in low pressure conditions. The SIT injects borated coolant through the cold leg if the system pressure decreases below the pressure of nitrogen gas filling the upper volume of accumulator.
- (ii) Containment system: The containment system consists of the containment building, containment isolation system, containment heat removal system, and combustible gas control system. The containment building provides physical barrier to prevent the release of radioactive products during the normal operation and postulated accidents. The containment isolation system isolates the containment by closing penetrated pipes during the accidents. The containment heat removal system aims to keep the integrity of containment by reducing inner pressure and temperature. The representative system is a containment spray system located at the upper part inside the containment, which sprays coolant pumped from RWST or containment sump. The combustible gas control system, or hydrogen control system, prevent the containment building from the potential damage by hydrogen explosion.
- (iii) Residual heat removal: The RHRS operates to remove the decay heat from the core and reduce the temperature of the reactor coolant to the cold shutdown temperature. The RHRS is typically a multiple use system with modes of operation for low pressure injection, shutdown cooling, suppression pool or containment sump cooling, and/or containment spray.
- (iv) Emergency feedwater: The decay heat removal from the primary system requires a heat sink, which is usually a steam generator cooled by feedwater. When the main feedwater system doesn't operate for some reason (e.g. loss of external power), the emergency feedwater system provides auxiliary feedwater to the secondary side of steam generator from a condensate storage tank or demineralized water storage tank.

Safety features of advanced reactors

The improvement of safety for the advanced reactors is introduced in a large variety of reactor designs including Generation III+ LWRs, mHTGRs, liquid metal reactors, and molten salt reactors, among other examples. These advanced reactor concepts have an enhanced focus on inherent safety characteristics relative to older Generation I, II, and III plants. The objective of inherent safety is to minimize the utilization of safety-related active systems and components (IAEA, 2007). In this section, the basic principles of safety and some examples of improved safety systems of the advanced reactors are briefly introduced. More detailed information is discussed in Stanculescu (2021).

The design of an advanced reactor should first satisfy the fundamental principles of safety discussed for the current-generation reactors (IAEA, 1999). Two principles may be considered as the basic requirements for the design of an advanced reactor. First, the defense-in-depth can only be complemented or operated by specific safety design features, but cannot be replaced by them. Second, the basic concepts for advanced reactor safety should include the control of the nuclear fission power and decay power, cooling of

the reactor in all scenarios, and containment of radioactive material, during the design, construction, and operation. In addition, the extended concepts of safety features are proposed to improve the safety of advanced reactors (IAEA, 1992). They include extension of plant design processes to include maintenance, simple and intuitive user-friendly design, reduced dependence on operator intervention, improvement of system reliability even in severe accident conditions, removal of high-risk event sequences, effective defense strategies from intentional damage or attack, reduction of uncertainty in safety and operational margins, and employment of passive safety systems. Based on these highly desirable extended safety features, various designs of advanced reactors have been developed. A passively safe advanced reactor is one whose design employs passive systems to function as the main safety systems in the reactor.

The main feature of advanced safety systems is the inherent operation by unavoidable natural physical phenomena. The definition of an inherent, or passive safety system is a system which is composed entirely of passive components and structures or a system which uses active components in a very limited way to initiate subsequent passive operation. The employment of passive safety systems significantly reduces the risk of nuclear reactor. Some specific examples of passive safety system for Generation III+ LWRs are described below (IAEA, 2009).

- (i) Safety injection tank: The safety injection tank is a coolant tank pressurized by nitrogen gas inside the tank, to supply auxiliary coolant to the core during a postulated LOCA. The operational principle is based on the difference between nitrogen gas pressure and primary system pressure.
- (ii) Core make-up tank: The core make-up tank, which is located above the core, injects coolant to the core by gravitational force. The upper valve of the core make-up tank provides the pressure balance between the tank pressure and primary system pressure, which allows enough head to drive the flow, regardless of the primary system pressure.
- (iii) Natural circulation inside the primary loop: If the primary loop is still closed during the accident, the natural circulation is achieved inside the primary system as long as the loop inventory is filled. The heat sink can be either the steam generator or an in-containment refuel water storage tank. The isolation condenser of the advanced BWRs adopts the same concept for the residual heat removal system, which is composed of closed circuit connected to the reactor vessel and the additional heat exchanger submerged in the cooling tank.
- (iv) Passive containment spray system: The external cooling of the containment building is achieved by natural circulation inside the passive containment spray system. The sprayed water is boiled by heat transferred from the surface of containment, and the steam is removed from the system along with the air. Inside the containment building, the steam generated from the core (or the entire primary system) condenses via external water and then flows down through the inner surface. This is followed by a natural circulation operational mode.
- (v) Containment cooling system: Locating external water pool above the containment building leads to natural circulation inside a closed loop between a heat exchanger in the containment building and the water pool. The natural circulation can continuously remove the heat from the containment building better than slow conduction across the containment building.
- (vi) Direct Vessel Injection (DVI) system is an advanced safety system to improve the challenges in injecting emergency coolant into cold leg by conventional safety injection system. DVI injects emergency coolant directly to the core instead of injecting it through the cold leg. After the AP-1000 adopted DVI for the improved safety system, US Advanced Pressurized Water Reactor (US-APWR) and Korea's Advanced Power Reactor 1400 (APR1400) followed by selecting the DVI system for delivering borated ECCS water from safety injection pumps into the core.

One prominent example of a demonstration of inherent safety in an advanced reactor is the EBR-II SHRT mentioned in this Chapter (Feldman et al., 1987; McFarlane, 2021). EBR-II was an experimental sodium-cooled fast reactor which operated for 30 years in the state of Idaho. The EBR-II SHRT examined the inherent capability to passively shutdown the reactor by steam load and primary flow control followed by decay heat removal by natural circulation of the primary coolant. The program demonstrated (Planchon et al., 1986) the inherent safety of EBR-II for a wide range of postulated accidents (Planchon et al., 1987) including loss-of-flow without SCRAM (LOFWS), loss-of-heat sink without SCRAM, and overpower accidents.

Similarly, the Fast Flux Test Facility (FFTF) was another reactor which demonstrated the inherent safety potential of liquid metal cooled reactor designs (Wootan and Casella, 2016; Zhang et al., 2017). FFTF conducted series of passive safety tests including steady state reactivity feedback tests, delayed pony motor trip, steady state natural circulation, controlled flow transient, LOFWOS with gas expansion modules (GEMs), inadvertent pump startup with GEMs, and core demonstration experiment safety tests. The results of the FFTF demonstrated the inherent safety features of sodium-cooled reactor designs including thermal expansion coefficients, Doppler coefficient, sodium density changes, and control rod driveline expansions that act as the passive negative reactivity feedbacks to counter a rise in sodium temperature.

Similar tests of inherent safety were also conducted in HTGRs. In the AVR reactor (German: *Arbeitsgemeinschaft Versuchsreaktor*), which was an experimental HTGR, the inherent safety features of HTGRs were examined under a pressurized loss of forced cooling accident (Ding et al., 2009). The experiments and simulations demonstrated the inherent control of reactivity by temperature change of the pebble bed core (Krüger et al., 1991). Similarly, the High-Temperature Engineering Test Reactor (HTTR) in Japan conducted tests for a control rod withdrawal in HTGRs (Nakagawa et al., 2004). The tests demonstrated another inherent safety of HTGRs that the fuel would not fail even if a large reactivity is inserted in a very short time. Additional fuel safety tests in the Nuclear Safety Research Reactor established useful limits for energy deposition in reactivity initiated accidents for HTTR fuel (Umeda et al., 2010). The inherent safety features of HTGRs were also examined in HTR-10 (Gou et al., 2018) under two postulated anticipated transients without scram (ATWS) accidents (Hu et al., 2006), including loss of forced cooling and Reactivity Insertion Accident

(RIA) tests (Boer et al., 2010). These examples of separate effects fuel safety tests are additional examples of the kind of testing needed to support reactor safety.

Molten salt reactor (MSR) designs achieve their inherent safety by the liquid state of fuel salt (the fuel cannot melt), strong inherent reactivity feedback characteristics, and low excess reactivity. This inherent capability was experimentally examined in Molten Salt Reactor Experiment (MSRE) (Guymon et al., 1966) which was an 8 MW_{th} fluid-fueled test reactor (Křepel et al., 2007). The fuel in some MSR designs can be dumped into a storage tank located below the core that can assure sub-criticality and decay heat removal.

Most of the inherently safe advanced reactor designs focus on the benefits of a small modular or integrated design. These design approaches enhance the inherent safety of the reactor and reduce uncertainties in the entire reactor system.

Conclusions

The first priority in the design of an NPP is always its safety in design, construction, operation, and eventual decommissioning. Lessons learned from past reactor accidents have led to the development of rigorous safety standards for the licensing and regulation of NPPs and to an enhanced focus on the passive safety characteristics of reactor concepts and systems. Various passive safety tests have been conducted on engineering facilities and experimental reactors, both in the United States and internationally. These tests build on the foundation of separate and integral effects tests required to generate the data necessary for model validation.

Although the current fleet is very safe, consistent with the Institute for Nuclear Power Operation's mission to promote the highest levels of safety and reliability—to promote excellence—in the operation of commercial nuclear power plants, ongoing studies leading towards a new level of safety in both existing and future nuclear reactors are under way.

Glossary

Actinides Any of a series of 15 consecutive chemical elements in the periodic table from actinium to lawrencium (atomic numbers 89–103). As a group they are significant largely because of their radioactivity. Although several members of the group, including uranium (the most familiar), occur naturally, most are man-made.

Conditioning Chemical improvement of nuclear waste prior to storage.

Deep Geological Repository An underground site, excavated from the surrounding rock formation, where nuclear waste is to be isolated from the biosphere for long periods of time.

Double Strata Fuel Cycle Proposed by JAERI (Japan Atomic Energy Research Institute), consists of the power reactor fuel cycle (Stratum 1) and the partitioning-transmutation cycle (Stratum 2). It consists of a reprocessing plant, a partitioning plant and a transmutation plant on a single site. In the power reactor stratum, only U and Pu are recycled. In the P-T cycle, the high level waste is partitioned (into four groups: TRUs, Sr-Cs, Tc, others), fabricated into fuel elements, and then transmuted in a dedicated accelerator driven system. In this scenario the MAs are separated from the power cycle due to the fact that they can be completely recovered and transmuted. Since the MAs are strong neutron emitters, this avoids potential problems of radiation shielding in the conventional reprocessing. The final HLW should contain mostly short-lived fission products, but also low concentrations of Pu and MA that escaped with process waste streams.

High Level Waste (HLW) Refers to the liquid waste from reprocessing which contains fission products and the minor actinides and, as a result, requires massive shielding and provision for cooling.

Minor Actinides (MA) Refers mainly to the elements neptunium, americium and curium. These minor actinides (MA) are produced as radioactive by-products in nuclear reactors. The term “minor” refers to the fact that they are produced in smaller quantities in comparison to the “major” actinide plutonium.

Mixed Oxide (MOX) Mixed oxide fuel containing plutonium instead of 235 U-enriched uranium as the main fissile component.

Partitioning Refers to aqueous or pyroprocesses which can be used to separate (partition) radioactive by-products or waste produced in nuclear reactors from the spent fuel.

Reprocessing General term for applying chemical and physical processes to used (spent) reactor fuel.

Used Fuel Nuclear fuel that has been used in a reactor.

Transmutation The conversion of a nuclide into a shorter lived or stable nuclide in a reactor or with an accelerator.

TRU Transuranic elements.

Nuclear waste

Contemporary nuclear energy systems are the result of extensive development efforts during which the technology has reached industrial maturity. Most of these developments have been concentrated on light water reactors (LWR) and their fuel cycles (OECD-NEA, 2003; Cochran and Tsoulfanidis, 1999).

Note that those parts of the fuel cycle that precede the use of the fuel in a reactor core are collectively called the front end of the nuclear fuel cycle (Crawford, 2021; Cochran and Tsoulfanidis, 1999). That portion related to the fuel after it has been removed from a reactor is called the back end of the nuclear fuel cycle. According to the front-end options, there are three well-developed fuel cycle technologies:

- Once-through (open) fuel cycle based on enriched uranium,
- Once-through (open) fuel cycle based on natural uranium,
- Fuel cycle with plutonium recycling.

The once-through (open) fuel cycle is the reference fuel cycle. It is the main alternative for Canada, Spain, Sweden, USA and some other countries. This scenario gives, with the present low uranium prices, the cheapest nuclear energy production. However, it implies that the residual fissile material content (1% Pu and 0.8% ^{235}U ; weight % of the metallic elements in the discharged fuel), as well as the remaining fertile material (^{238}U), of the spent fuel will not be recovered and becomes a waste material (Cochran and Tsoulfanidis, 1999).

Radioactive wastes comprise a variety of materials requiring diverse types of management to protect people and the environment (Baetsle, 2001; Cochran and Tsoulfanidis, 1999). They are normally classified as low-level (LLW), intermediate-level (ILW) or high-level wastes (HLW), according to the amount and types of radioactivity in them:

- Low-level waste (LLW) comprises the bulk of waste from the nuclear fuel cycle. It comprises paper, rags, tools, clothing, filters etc. which contain small amounts of mostly short-lived radioactivity. It does not require shielding during handling and transport and is suitable for shallow land (near surface) burial. To reduce its volume, these wastes are often compacted or incinerated before disposal. Disposal sites for low-level waste are in operation in many countries. Worldwide they make up 90% of the volume but have only 1% of the total radioactivity of all radioactive wastes.
- Intermediate-level waste (ILW) contains higher amounts of radioactivity and normally requires shielding. Shielding can be barriers of lead, concrete or water to give protection from penetrating radiation such as gamma rays. Intermediate-level wastes typically comprise resins, chemical sludges and metal fuel cladding, as well as contaminated materials from reactor decommissioning. It may be solidified in concrete or bitumen for disposal. Generally short-lived waste (mainly from reactors) is buried.
- Operating a nuclear reactor implies fissioning ("burning") the fuel, producing fission products, such as various isotopes of barium, strontium, cesium, iodine, krypton and xenon (Ba, Sr, Cs, I, Kr, and Xe). Many of these light nuclides formed as fission

products within the fuel are highly radioactive, and hence short-lived. In addition to nuclides formed through fissions, neutron capture reactions transform fertile actinides into various transuranic (TRU) isotopes. These include ^{239}Pu , ^{240}Pu and ^{241}Pu , as well as others arising from ^{238}U by neutron capture and subsequent beta decays. Looking at the backend of the fuel cycle, all these nuclides are radioactive and remain within the used fuel composition when it is removed from the reactor. The transuranic nuclides constitute the most of the long-lived portion of HLW. The long-term hazard of used fuel and HLW is associated with actinides, particularly the TRUs, while the short and long term risks are due to the mobility of fission products in the geosphere and the possibility of their entering the biosphere. During the first 150 years after fuel discharge, the fission products ^{137}Cs and ^{90}Sr determine the radiotoxicity and the heat emission. From 150 years till 250,000 years the plutonium isotopes are the main contributors to the radiotoxicity. Beyond 250,000 years ^{237}Np emerges together with the daughter products of uranium. One may expect developments aiming towards solutions improving the back-end of the nuclear fuel cycle, i.e. management of transuranics in the used fuel.

Partitioning and transmutation (P&T) of transuranic nuclides (TRU), in particular minor actinides (MA), in nuclear reactors offer benefits of significant reductions or complete conversion of long-lived HLW TRU inventories into short-lived fission products. Thus, these technologies carry a potential of reducing expectations for future nuclear waste repositories.

Disposition of nuclear waste

Most countries with nuclear facilities planned or operational have active programs seeking geological disposal sites. The objective is to locate areas where multiple reliable barriers can be established between the wastes and the environment (Cochran and Tsoulfanidis, 1999; Hewitt and Collier, 2000; Mekki, 2021; Ewing and Park, 2021). Some of the barriers, both natural and engineered, being considered are:

- Encapsulate in an insoluble form of waste (glass, Synroc or UO_2) that is immobilized either as ceramic oxide (e.g. the spent fuel itself) or through vitrification (separated HLW from reprocessing);
- Seal in corrosion-resistant containers (stainless steel or copper);
- Immobilize in wet rock packing with bentonite clay to inhibit groundwater movement and insulate from minor earth movement;
- Locate deep underground (e.g. 500 m deep) in stable rock formations.

Synroc is an advanced ceramic substance principally comprising three natural titanate minerals which are geochemically stable and which together have the capacity to incorporate into their crystal structures nearly all of the elements present in high-level radioactive waste, thereby immobilizing them. Three types of geological structures are being widely studied for this purpose: hard crystalline rocks, clays and rock salt beds (Cochran and Tsoulfanidis, 1999; Lamarsh and Baratta, 2001).

Suitable locations have been defined in several countries and the sites are now undergoing detailed evaluation. Most approaches plan to utilize conventional mining techniques involving shaft-sinking and development of extensive drives and rooms. These will provide sufficient area for the canisters to be placed in suitably-spaced holes in the floor on each level, or some other arrangement (IAEA, 2005).

One purpose-built deep geological repository is now operating in New Mexico, USA, but this is only for long-lived military wastes: The WIPP – Waste Isolation Pilot Plant in Lea County, located in the remote Chihuahuan Desert in a salt formation, began operations on March 26, 1999.

Moving forward with an integrated waste management strategy, the U.S. Department of Energy (DOE) established the policy moving to a long term solution. The plan is to setup interim storage facilities first, and then move to a long-term repository. The strategy is sufficiently flexible to incorporate advanced fuel cycles. As a result, to date there has been no practical need for final HLW repositories, as surface storage for 30–50 years is first required so that heat and radioactivity can dissipate to levels which make handling and storage easier (Cochran and Tsoulfanidis, 1999; Department of Energy, 2021). Extensive spent fuel evaluations have been conducted to fully characterize compositions, storage conditions, dry cask loading sequences of interim storage options, and expectations for permanent disposal. These efforts results in the spent fuel database and associated tools for waste management evaluations (Yancey and Tsvetkov, 2014). The analysis identified and quantified variations in the inventory data showcasing both fidelity of older historical data as well as the need for regular characterization of accumulating inventories (Yancey and Tsvetkov, 2015).

Reprocessing

Reprocessing involves dissolving the spent fuel to enable the re-usable plutonium and uranium content to be separated from the residual waste fission products and actinides. The fuel assemblies are chopped up and placed in nitric acid. This enables the fuel content, which dissolves in the acid, to be separated from the insoluble zirconium alloy or stainless steel cladding (Cochran and Tsoulfanidis, 1999; Marin, 2021).

The solution of uranium, plutonium, other actinides and fission products is then chemically treated in a series of stages which are designed to produce solutions of plutonium nitrate and uranyl nitrate of high chemical purity. The waste products (other actinides, fission products and unwanted impurities) are stored as a highly radioactive solution in water-cooled, double-walled high-integrity stainless steel tanks before further conditioning. The separate solutions of uranyl nitrate and plutonium nitrate are further processed. The uranium can be converted to uranium dioxide for storage or for the production of new fuel, by blending with fissile material or conversion to uranium hexafluoride for return to the enrichment plant. The plutonium nitrate is converted to plutonium dioxide for storage or for incorporation into Mixed Oxide fuels for thermal or fast reactors (Baetsle, 2001).

Conditioning of the wastes produced by reprocessing is a well established operation that has been rigorously examined and approved by regulatory authorities in several countries. The removal of the plutonium and the uranium via reprocessing reduces the volume of high level waste, but leads to the production of low and intermediate level wastes.

Following conditioning and, in most cases, interim storage for a number of decades to allow further reduction of radioactivity and heat generation, vitrified HLW, suitably encased, can be transported to and placed in a deep geological repository. Here, it can be held under supervision and, when considered appropriate, sealed off permanently. The glass matrix in which the highly radioactive wastes are incorporated, the method of encapsulation and the geological formation chosen to isolate the radioactivity from the biosphere, are carefully selected to ensure long term safety (Cochran and Tsoulfanidis, 1999; Hewitt and Collier, 2000; Bruno, 2021).

Partitioning and transmutation

The role of nuclear energy in a sustainable energy future has multiple facets, a significant number of which relate to the nuclear fuel cycle. Many sustainability issues are associated with the fuel cycle, e. g. use of natural resources, economics, wastes, public acceptance, proliferation resistance, and etc. (Brogli and Krakowski, 2002; OECD-NEA, 2001; Wydler and Baetsle, 2000).

Partitioning and Transmutation (P&T) is a complex technology which implies the availability of advanced reprocessing plants, facilities for fuel fabrication of transuranic elements (TRUs) and irradiation facilities beyond the present facilities (OECD-NEA, 2003; Salvatores, 2005; Salvatores et al., 2004, 1994; Boullis and Charbert, 2021).

Partitioning is to a certain extent a broadening to other nuclides of the current reprocessing technique which has been operating at industrial level for several decades and for which the main facilities exist or can easily be extrapolated from present day nuclear plants (Jackson, 2003).

Partitioning is the technology which can be considered as a form of “super - reprocessing” by which, in addition to U, Pu and Iodine (^{129}I) also the Minor Actinides (MA) and the Long lived Fission products (LLFP: ^{99}Tc , ^{93}Zr , ^{135}Cs , ^{107}Pd and ^{79}Se) would be extracted from the liquid high level waste (Baetsle, 2001; Jackson, 2003).

The closed fuel cycle with P&T incorporated is without any doubt the most comprehensive approach. It requires very important and dedicated fuel cycle and reactor facilities which go far beyond the presently existing nuclear technology. Especially, the transmutation approach calls for the development of FR-burners and accelerator-driven systems (ADS) which may take 20 to 30 years before these are industrially available (Wydler and Baetsle, 2000; Boullis and Charbert, 2021; Krepel, 2021; Abderrahim and De Bruyn, 2021).

Fig. 1 illustrates typical nuclide transformations in a legacy PWR, assuming the fuel was irradiated by thermal neutrons. The use of higher energy neutrons would lead to enhanced fissions of TRUs ultimately reducing their inventories (Tsvetkov et al., 2008).

Moving towards sustainable nuclear energy, the transmutation strategy is to close the fuel cycle of conventional, i.e. LWR-dominated, reactor parks also for the MA by recycling all actinides homogeneously or heterogeneously in existing and innovative reactor types. If the fuel reprocessing losses are sufficiently small, complete closure of the fuel cycle would result in a considerable reduction of the actinide content, and hence the long-term radiotoxicity, of the HLW. Innovative reactor types and new recycle infrastructures, including the pyrochemical or “dry” reprocessing technique, would be necessary, especially for burning highly concentrated TRU and minor actinides (Brogli and Krakowski, 2002; National Research Council, 2008).

If some of the long-lived fission products could also be transmuted or separately conditioned, the radiotoxicity of the remaining HLW would decay within a few hundred years, meaning that repository designs for such HLW may meet licensing requirements more easily. Thus, since the radiotoxic nuclides in the HLW can only partially be eliminated, transmutation does not make geologic disposal concepts superfluous, but must be considered as a complementary waste management method which may ease the design and licensing requirements for geologic repositories (IAEA, 2004; Salvatores, 2005).

However, with regard to the repository requirements for vitrified HLW, it should be noted that the total mass and the initial heat production of the vitrified waste are dominated by the fission products and, hence, mainly depend on the total thermal energy produced by nuclear reactors. Moreover, due to the non-linear relationship between the actinide content of the waste matrix and the repository release rates, actinide mass reductions achieved by transmutation do not necessarily translate into proportional actinide risk reductions (Baetsle, 2001).

Fig. 1 Thermal neutron induced transformations in the reference legacy-PWR fuel.

Considering various reactor options and related fuel cycle scenarios, there are several feasible fuel cycle development directions:

- Once-through LWR-to-HLW;
- TRU-burning LWR-to-FR-to-HLW;
- TRU-burning LWR-to-ADS-to-HLW;
- FR-to-HLW.

In the conventional LWR fuel cycle, the radiological hazard of the depleted uranium arising from the enrichment process and the recovered irradiated uranium (irradiated enriched uranium from LWR-UOX fuel and irradiated depleted uranium from LWR-MOX fuel) is only of secondary concern. However, in P&T scenarios with fully closed fuel cycles, the long-term radiotoxicity of this residual uranium becomes comparable with the HLW radiotoxicity (Brogli and Krakowski, 2002; Cochran and Tsoulfanidis, 1999; Kolb and Martinsen, 2003).

Whereas all transmutation strategies with fully closed fuel cycles perform similarly with respect to the resource efficiency and environmental friendliness parameters, different requirements and consequences arise for the establishment of the fuel cycle. In this context, important parameters are the TRU inventory of the fuel cycle and the decay heat and neutron source strength of the fuel.

The analyses show that, among the different transmutation strategies, TRU burning in ADS is associated with the lowest TRU inventory and hence the lowest activity inventory. This means that this strategy can respond flexibly to unexpected changes in the nuclear energy scenario and has safety advantages (OECD-NEA, 2002; IAEA, 2004; Nakagawa, 2003).

On the other hand, the decay heat of the ADS fuels is well beyond the limit for which the radiation stability of the organic extractant in the aqueous process can be guaranteed. For these and all other systems with fully closed fuel cycles, the less developed pyrochemical reprocessing ("dry" reprocessing) is the appropriate reprocessing method because it circumvents unnecessary separation processes (only fission products are extracted) and can handle highly active product streams without major radiation degradation (OECD-NEA, 2002).

Thus, P&T techniques could contribute to reducing the radioactive inventory and its associated radiotoxicity by a factor of 100 or more and to reducing the time needed to approach the radioactivity levels of the raw materials: uranium and its equilibrium decay products originally used to produce energy. Great scientific progress has been made in metallic barrier building and in mining technology. Nobody can fully guarantee total confinement of radiotoxic materials in human-made structures beyond 10,000 years.

The reduction of the solubility of long lived radio-nuclides in underground aquifers may be a first step in reducing their migration. Partitioning from nuclear waste streams and conditioning of long lived radio-nuclides into stable matrices may be a second step in this direction before disposal. The economic implications of a P&T policy are not negligible, however, and the responsibility associated with this societal choice has to be taken by the present generation for an unknown number of future generations. The decision to reduce the radiotoxic inventory of nuclear material by transmutation is an important one that has to be taken by the responsible authorities.

The main goals of P&T are:

- A reduction of the hazard associated with spent fuel over the medium and long term (> 300 years) by a significant reduction of the inventory of plutonium and MAs.
- A reduction of the time interval required to reach a reference level of radiotoxicity inventory by recycling transuranic elements (TRUs).
- A decrease of the spent fuel volume by separation of uranium to enable more efficient storage or disposal. This should result in an increase in the effective capacity of a final repository. However, this approach might require special handling of strontium and cesium after partitioning.

Evaluations confirm the following general observations:

- Radiotoxicity: P&T must first be concerned with the actinides, MAs – Am and Cm. The toxicity of the fission products is two orders of magnitude smaller after 10^3 years.
- Repository risk: The mobile fission products are more important than the actinides. The fission products, ^{129}I , ^{135}Cs , ^{79}Se , ^{99}Tc , ^{126}Sn , are dominant dose contributors.
- The fission product risk peaks between 10^4 and 10^6 years after the closure of a repository, whereas an actinide risk arises “only” after one million years.

The major potential benefits of application of P&T technologies are:

- Resource conservation by making maximum use of the energy available from the primary fuel material, uranium. This has been pursued through the separation of re-useable uranium and plutonium from spent nuclear fuel by means of reprocessing. The current price of uranium relative to fossil fuels makes this uneconomic and there is perceived to be limited value in extending reprocessing operations to this end alone;
- Reduction of the heat generation of wastes. Repository designs can incorporate temperature limits designed to guard against thermal degradation of the surrounding rock and prevention of boiling that impedes natural groundwater movements. The benefit derives from enlarging the capacity of a repository and reducing the number of sites required. This aim underpins R&D in the USA in both partitioning and transmutation;
- Reduction of radiotoxicity of waste. By transmuting elements, such as plutonium and americium, it is theoretically possible to transform the spent fuel so that it will decay to the activity of the original uranium in a few hundred (rather than tens of thousands) years, reducing the period over which it is a hazard.

All these potential benefits have to be judged against other forms of management. If direct disposal, for example, is a reliable means of isolating the wastes from the environment (thus preventing the escape of the more mobile radionuclides most of which are not suitable for transmutation) then significant additional cost of transmutation technology would have little practical benefit in reducing hazard (Wydler and Baetsle, 2000).

Nuclear fuel cycle problems and challenges

Aqueous reprocessing

Considering various P&T options and technologies, there are many problems and challenges that should be mentioned:

- Current proposals for P&T technology rely on the aqueous (PUREX-type) reprocessing of spent fuel as a preliminary step preceding minor actinide partitioning. The drastic increase of the plutonium content from 15% up to 43% and the fuel burn-up from 80 GWd/tHM up to 210 GWd/tHM for fast reactor concepts make aqueous reprocessing more difficult because of the low solubility of plutonium and the radiation damage to the organic extractant (tributyl phosphate).
- The present state-of-the-art in aqueous reprocessing based on the PUREX process is almost satisfactory with regard to uranium and plutonium separation. Recovery yields of nearly 99.7% have been achieved and 99.9% is potentially achievable in a near future. However, reprocessing of industrial quantities of LWR-MOX and FR-MOX (FR – Fast Reactor) within short cooling times will require gradual adaptations of the PUREX flow-sheet and involve the construction of additional extraction rigs.
- The decay heat of the separated plutonium fraction enters the organic phase and remains in contact with the actinide fraction (U, Pu, Np) until separation and purification of the major actinides occurs. The ^{238}Pu concentration in the plutonium stream is the main source of radiation damage to the tributyl phosphate extractant, a strong source of neutrons in the separation plant, and an additional radiolysis agent during the oxalate precipitation and conversion to PuO_2 . On the other hand, the high ^{238}Pu concentration in the separated PuO_2 for the same reasons (heat, spontaneous neutrons) improves the nonproliferation resistance of the product during storage.
- The MOX fuel fabrication will have to adapt its handling technology to reduce the radiation dose to the workers in the plant and during the transport of MOX fuel assemblies.
- The separation of the MA is currently under intense investigation. The separation of the bulk of ^{237}Np from the aqueous product solution during the reprocessing operations is technically feasible but requires an adaptation of the first cycle extraction flow-sheet. The residual ^{237}Np which goes directly to the HLW solution could, in principle, be recovered by recycling the HLW

solution through a secondary recovery cycle after a valence adjustment. With liquid extraction processes, the separation yield can be increased up to the desired value of 99.9% by increasing the number of extraction stages.

- The separation of americium and curium is much more difficult, but considerable progress has been made during the past decade. Bulk separation of MA together with lanthanides has been demonstrated under hot-laboratory conditions. The separation of MA from lanthanides, however, remains an obstacle for the industrial up-scaling of Am-Cm separation from HLW. Several promising laboratory methods have been tested. Yields of 99% and 97.6% have been achieved for americium and curium, respectively. Further improvements are necessary in order to include these methods in a cycle of multiple reprocessing.

Pyrochemical reprocessing

The proliferation risk potentially associated with the clean plutonium produced by the aqueous reprocessing has drawn the attention on the pyrochemical reprocessing which makes it difficult to separate individual TRU elements. Whereas the pioneering work was performed by ANL in the USA, most of the recent advances have been made in Russia and Japan. In the Russian Institute of Atomic Research (RIAR), a pyrochemical process has been demonstrated with highly irradiated spent oxide fuel with burn-ups of 210–240 GWd/tHM (OECD-NEA, 2003; Cochran and Tsoulfanidis, 1999; Jackson, 2003).

Good results were obtained during the demonstration. The recovered PuO_2 are mixed with UO_2 and processed by vibropacking into fresh FR-MOX fuel. Pyrochemical reprocessing of metallic fuel was developed in the USA in the framework of the integral fast reactor (IFR) program with capability for actinide burning. Recovery yields of 95% for uranium and 99% for mixtures of uranium and minor actinides have been obtained on laboratory and pilot-plant scales (Jackson, 2003).

The advantages and disadvantages of the pyrochemical reprocessing can be summarized as follows:

- Highly concentrated TRU product streams can be handled without major radiation degradation of the reagents, allowing the facilities to be more compact than aqueous reprocessing facilities for the same TRU throughput. Because of the absence of water, much smaller criticality risks during purification and metallic fuel re-fabrication arise when processing industrial quantities of TRUs.
- Since all TRU elements remain together throughout the process, the proliferation risk is much reduced. The separation of the TRUs from the lanthanides, however, is difficult, requiring the development of multistage countercurrent extraction using highly corrosive reagents at high temperature. The most challenging issue is the selection and industrial manufacture of corrosion resistant equipment which must be designed for remote operation and maintenance.
- For spent LWR-UOX fuel, a genuine pyrochemical process has to cope with the problem of the elimination of the uranium, which is the major constituent of the LWR fuel. Therefore, a mixed approach using a (P)UREX-type process for uranium-neptunium elimination has been selected as the first step. Fluoride volatility has also been suggested as an alternative, but the mixed volatility of U-Pu and zirconium leads to complex waste streams which can be difficult to control.
- Starting from metal or nitride TRU fuel, a complete pyrometallurgical process involving a series of electro-refining steps in a wide range of molten salt baths has recently attracted much interest throughout the nuclear research communities in the USA, Russia, Japan and France. Most of the respective flow-sheets remain in the pre-conceptual phase and will require several decades of R&D to become a mature technology.
- Whereas the aqueous reprocessing consists of an independent industrial process which supports a large reactor park and can operate independently on continental or even world scales, the pyrochemical process will predominantly be applied in small facilities installed in the immediate vicinity of the reactors.
- However, in the long-term, pyrochemical reprocessing will become indispensable, if very hot fuel has to be multi-recycled in fast reactors or accelerator-driven systems on an industrial scale with a limited out-of-pile inventory.

Actinide transmutation

Depending on regional boundary conditions and political factors, countries with P&T programs have developed different transmutation strategies:

- The evolutionary approach, adopted mainly in Europe and Japan, aims at closing the fuel cycle in successive steps, starting with the recycling of plutonium in LWRs and later in fast reactors using conventional reprocessing and MOX fuel technology, and finally complementing the system with a dedicated P&T cycle which features MA burners with fast neutron spectra.

This approach has the advantage that it can respond flexibly to changes in the priorities for plutonium and minor actinide management, and that new technologies have to be developed only for a comparatively small number of MA burners which support a large system of conventional LWRs and fast reactors.

An option has been explored to perform the transmutation of MA in the form of targets to be loaded in critical cores of a “standard” type. The mode of recycling has been called “heterogeneous”, the potential advantage being to concentrate in a specific fuel cycle the handling of a reduced inventory of MA (separated from Plutonium).

- The innovative approach, first suggested in the USA, aims at co-processing plutonium and MA to avoid the use of technologies with a potentially high proliferation risk. After the initial separation of the uranium from the LWR spent fuel, the unseparated

transuranic actinides are recycled in a transuranic burner with a closed fuel cycle based on pyrochemical reprocessing. Compared with the double strata strategy, the number of burners in the equivalent system is four to six times larger, but the burners are not subjected to a (fast) neutron-spectrum condition. Nevertheless, most of the currently evaluated critical and sub-critical transuranic burners feature a fast neutron spectrum.

The homogeneous recycling has been explored in U.S. The concept is mainly designed to produce energy, making an optimized use of resources and using a robust reactor and fuel cycle layout. The fuel cycle does not imply the separation of Pu and MA.

The concept can accommodate in principle several options in terms of reactor size, reactor coolant, waste-forms, etc. In general, the homogeneous recycling has equivalent performances for whatever the type of fuel in the fast reactor. However, the consequences on the fuel cycle have to be taken into account and their impact evaluated.

The transmutation of an actinide is completed, when the transformation chain, which involves “generations” of neutron reactions and radioactive decays, terminates with a fission. In order to get a net MA destruction yield, the elimination of the nuclide must exceed the internal production. Conventional LWRs cannot be used to decrease significantly the Np and Am radiotoxic inventories resulting from LWR- UO_2 reprocessing as neutron capture reactions dominate the nuclear transmutation processes. The presence of highly active α -emitters (especially ^{244}Cm) in irradiated targets make multi-recycling nearly impossible (Baetsle, 2001; IAEA, 2004; Salvatores, 2005).

The low MA transmutation capability of LWRs has been demonstrated by different R&D groups. It has been shown that by following the once-through irradiation, only with very long irradiations (20 to 30 years) and with higher ^{235}U enrichment, significant results could be obtained.

The stabilization of the TRU inventory with LWRs is only possible by generalizing the use of LWR-MOX fuel with an increased ^{235}U enrichment in the entire reactor park. It would profoundly influence the fuel fabrication needs for LWR-MOX and require additional ^{235}U enrichment capacity (Kolb and Martinsen, 2003; OECD-NEA, 2001).

Complete elimination of the actinide inventory by neutron irradiation can only be accomplished in a fast neutron spectrum, of either “critical” or “subcritical,” reactor. The real net reduction results from fission and is consequently proportional to the burnup of the fuel or target. High burnups are the prerequisite condition for a reasonably fast reduction pace but involve on the other hand the industrial implementation of the most difficult reprocessing operations on very “hot” nuclear materials (OECD-NEA, 2002).

The maximum burnup obtainable in a fast neutron spectrum device (FR or ADS) is in principle not limited by the fissile material content, since all TRU's are to a certain extent fissionable, but by the resistance to fast neutron radiation damage of the cladding material expressed in “displacements per atom.” If the fast neutron dose exceeds 200 dpa the stability of the cladding material is at stake and the highly irradiated fuel or target (150–250 GWd/tHM) will have to be withdrawn from the reactor and recycled or disposed of (OECD-NEA, 2002).

From neutron economy considerations, it follows that the complete closure of the fuel cycle of a fission-based nuclear energy system is eased by integrating fast spectrum devices into the system. From the viewpoint of both resource utilization and actinide waste production, the ideal system is a single component system based only on fast reactors with a fully closed fuel cycle. It is well known that such a system has the potential of fissioning natural uranium and thorium resources with a close to 100% efficiency while producing only a very small amount of actinide waste.

Fission product transmutation

The neutron capture process is currently the only promising nuclear reaction for transmuting fission products. Other processes which have been proposed in the past rely on technologies which are still at a very early stage of development (e.g. fusion neutron sources) and generally suffer from a poor energy balance. The capture process consumes neutrons but, theoretically, fast reactors could deliver enough surplus neutrons to allow the potentially troublesome long-lived fission products to be completely transmuted to shorter-lived or stable species.

The transmutation of a fission product makes sense only if the reaction rate (microscopic cross section times neutron flux) is higher than the natural decay rate of the nuclide (Cochran and Tsoulfanidis, 1999). With the practically achievable neutron fluxes, this condition cannot be met for the most abundant fission products, ^{137}Cs and ^{90}Sr with half-lives of only about 30 years, i.e. these fission products are “non-transmutable.” However, since their radioactive life is limited to less than 300 years, they can be safely enclosed using engineered barriers only. On the other hand, the fission products determine the size of the vitrified waste repository which, consequently, cannot be much reduced by P&T operations.

The fission products which influence the long-term risk of a repository are, in order of radiologic importance, ^{129}I , ^{99}Tc , ^{135}Cs , ^{93}Zr , and ^{126}Sn . Activation products (^{14}C and ^{36}Cl) can also contribute to the dose. Obviously, the relative contribution of these nuclides to the integral risk varies according to the type of repository host rock. In the following, the problems associated with the transmutation of these five fission products are discussed separately. It should be noted that the determination of the separation yield and the decontamination factor (DF) for HLW depends to a great extent on policy decisions and that, depending on the nuclide, special conditioning and confinement is an alternative to transmutation.

The primary risk of geologic repositories is related to the release of long-lived fission products. For the long-lived fission products, the goal is to transform them into shorter-lived or stable species by means of neutron capture reactions. With the exception of ^{99}Tc , however, the transmutation of long-lived fission products appears to be difficult because of low neutron reaction cross-sections

and the necessity of isotopic separations. This means that, for most fission products, special conditioning and confinement is the only practical method to reduce the radiological impact.

It should be noted that the transmutable fission products represent only a small fraction of all fission products and that the vitrified waste mass, which is primarily determined by the fission products, therefore, cannot be much reduced by P&T operations. A combined transmutation-conditioning strategy for the long-lived fission products, however, would allow easing the licensing requirements for vitrified waste repositories because the geosphere barrier would no longer have an important safety function.

Generation IV transmutation impacts

The Generation IV systems considered are the thermal-spectrum VHTR and SCWR, and the fast-spectrum GFR, LFR, and SFR. The base fuel cycle for the thermal reactor concepts (VHTR and SCWR) is a once-through fuel cycle using low-enriched uranium fuels. The higher burnup and thermal efficiency of the VHTR gives an advantage in terms of heavy-metal waste mass and volume, with lower decay heat and radiotoxicity of the spent fuel per electrical energy produced, compared to a PWR. Fuel utilization might, however, be worse compared to the PWR, because of the higher fuel enrichment essential to meeting the VHTR system design requirements. The SCWR concept also features improved thermal efficiency; however, benefits are reduced by the lower fuel discharge burnup (National Research Council, 2008; OECD-NEA, 2001; Stanculescu, 2021).

The base fuel cycle for the fast reactor concepts (SFR, GFR, and LFR) is a closed fuel cycle using recycled TRU and depleted uranium fuels. Waste management gains from complete recycle are substantial, with the final disposition heat load determined by processing losses. The base Generation-IV concepts allow consumption of ^{238}U significantly extending uranium resources (up to 100 times).

For both thermal and fast concepts, recent design studies have pursued the development of dedicated burner designs. Fig. 2 illustrates typical neutron spectra in Generation IV helium-cooled HTRs and SFRs comparing their conditions to a generic Generation II PWR neutron spectrum.

Preliminary results suggest that a burnup of 50–60% is possible in a HTR burner design using non-uranium (transuranics) fuel. However, practical limits related to higher actinide buildup and safety impact may limit the extent of TRU burning in thermal reactors. Fast burner designs have been developed for both conventional and high TRU content fuel forms. In general, the conversion ratio can be varied within a system by changing the uranium loading. Recent studies indicate a low conversion ratio (0.25) SFR retains the favorable passive characteristics of conventional designs, and the cost is similar.

Fig. 2 Spectral conditions in reactor environments with light-water (PWR), graphite (HTR) and sodium (FR).

Transmutation systems and safety

At a basic level, there are six safety functions to be fulfilled when operating fissioning systems (Wydler and Baetsle, 2000).

- The nuclear fuel must remain contained within a controlled space because of its radiotoxicity; this is traditionally accomplished by use of multiple containment barriers.
- Shielding must be kept in place between fissioning and fissioned fuel and humans to avoid suffering radiation damage.
- A heat-transport path must be in place to carry energy away from the fissioning medium to a heat sink; usually an energy conversion plant.
- The rate of release of fission energy in the chain reacting medium must be regulated to remain in balance with the rate of energy delivery to the heat sink, so as not to overheat the containment barriers around the fuel and challenge their integrity; a capacity to store heat in the reacting medium and heat transport channel will buffer mismatches of short duration or small amplitude.
- Since some 5% of the energy liberated from each fission event is initially retained in nuclear bonds of unstable fission products, and since these fission products subsequently decay according to their natural radioactive-decay time constants, a means must be provided for transporting heat from the fission products and transuranics in the fuel for all times subsequent to the fission event. Failure to satisfy the latter two safety functions could lead to overheating of the fuel with the potential to defeat the integrity of the containment and shielding.
- Operation of the fissioning device in a quasi steady state mode requires a balance of neutron production and destruction rates from one fission chain generation to the next – even as the composition of the chain reacting medium changes due to transmutation and as the absorption, leakage, and neutron production properties of the fissioning medium change with changes in composition and temperatures.

Strategies to fulfill the six basic safety functions have been developed and refined over many years for conventional (critical) reactors. The strategy employs defense in depth such that any single failure will not defeat the strategies for meeting safety functions and thereby result in unacceptable release of radiotoxicity; multiple barriers (fuel cladding, primary coolant boundary, and reactor containment building) are used to prevent release of radiation even under accident conditions. Highly reliable (diverse and redundant) systems for controlling and terminating the chain reaction are used to match heat production to removal rate. Highly reliable, redundant/diverse systems for decay heat removal are provided. High quality construction and verification norms minimize manufacturing flaws, and rigorous maintenance, formal procedures, and exhaustive training and certification of operators and maintenance workers are used to minimize the occurrence of human error which could subvert the achievement of the safety functions. Once safety is “designed into” the system, its efficacy is judged by an independent safety regulative authority on a plant-by-plant basis prior to deployment and during its operation.

Economic considerations

It seems at present the only grounds for considering reprocessing would be to improve the overall situation for long-term storage of nuclear fuel. Calculating the costs and benefits would require an in depth analysis of factors such as the cost of reprocessing versus the benefits of a smaller depository. The likely high costs of transmutation, if and when it becomes commercially feasible, would have to be weighed against the presumably lower cost of burying the fuel for the long-term in an appropriate geological depository (OECD-NEA, 1994, 2001).

Engineering cost estimates would be a factor in decisions on which option to pursue but social, political and economic considerations would be likely be decisive.

Given the uncertainties that surround the technology, it is not surprising to find that there are no detailed cost estimates available. At present, reliance has to be placed on very broad assessments.

If the technology is to be linked to a future power reactor program, there are several items that would have the effect of raising the cost of production of the end product, namely, electricity. These include:

- Additional fuel manufacture costs because of the need to produce targets;
- Reduced power output from a reactor because the targets will carry a reactivity penalty;
- Additional reprocessing costs because of the additional plant and processing required.

If P&T was to be applied in the absence of a power reactor program, ADSs would need to be built. As no fully developed ADS conceptual design yet exists, it is not possible to offer even a crude estimate, but clearly implementation could prove to be very expensive indeed.

Environment, transportation, reprocessing safety

Environment

The environmental issues of reprocessing are closely related to the economic issues. It would seem that minimizing the environmental impact over the entire nuclear fuel cycle would be a more plausible optimization criterion instead of minimizing its total

cost. The complicated fuel cycles aimed at consuming most of the radioactive isotopes arising from spent fuel, of the type being studied in particularly Europe, involve more than one reactor and multiple reprocessing steps. They need to be examined very carefully, particularly in terms of the resulting reprocessing wastes. Comparisons need to be made with the environmental impacts of long-term geological storage to ensure that the radiotoxicity and net radioactive burden to the biosphere were really decreased by reprocessing (OECD-NEA, 2001; Wydler and Baetsle, 2000).

During the early stages of the Cold War in the 1950s and 1960s, an intense nuclear arms race gave rise to very large scale processing of nuclear fuel to extract plutonium. This fuel was irradiated in purpose-built reactors. Virtually no attention was paid to the environment in what many on both sides perceived to be a contest for survival. The outcome was very large quantities of poorly stored and badly characterized reprocessing wastes needing costly remediation in locations like Hanford in the US and Chelyabinsk in Russia. Therefore, the issue is whether reprocessing is fundamentally an environmentally risky business or whether it was just done badly in the Cold War period but now is sustainable in a civilian context.

La Hague (France) pursues a rather open approach and regularly publishes the occupational exposure of its staff and analyses of seafood, local produce and other biosphere radiation measurements. La Hague's record of minimal environmental impact, at least in the short term, indicates that civilian nuclear fuel reprocessing can be done in an environmentally responsible manner.

Transportation

Reprocessing requires the transportation of nuclear fuel from the reactor sites to the reprocessing plants and the subsequent transportation of the products (plutonium, uranium and fission products) in the case of commercial plants, back to their countries of origin. This is now done routinely throughout the world using massive containers to shield persons from the high levels of radiation from their contents. These containers are specially engineered to withstand the worst rail and road accidents that can be hypothesized. Severe tests such as long exposure to high temperature fires and dropping from heights onto an unyielding surface, and onto hardened steel pins, must be passed before the containers are approved for use. Spectacular tests such as train crashes have also been carried out (Wydler and Baetsle, 2000).

Security in the transportation of materials such as plutonium is also stringent. Certain government agencies specialize in securing such shipments and Japan, for example, has built armed vessels especially for the transport of materials that might be used in weapons.

The record on transportation has been excellent in terms of both radiation safety and security. Evidently transportation to and from reprocessing facilities can be done safely and the primary issue is likely to be the cost of specialized transportation facilities and personnel rather than technical feasibility.

Reprocessing safety

The early days of reprocessing saw many accidents within the plants. The organic solvents used must be carefully handled and fires can occur even in operations such as encasing low level radioactive wastes in bitumen as happened in 1995 at TRP (Japan).

It was found that as the technology matured that the key to preventing these incidents is a continuous emphasis on safety culture among the employees combined with a high degree of quality control. The consequences of such accidents are mitigated by the design of modern reprocessing plants, which retain and contain any radioactive materials released within thick-walled vault structures (IAEA, 2004; Salvatores et al., 2004; Wydler and Baetsle, 2000).

A particularly damaging reprocessing accident occurred in 1957 at Kyshtym, some 80 km from Chelyabinsk. Kyshtym was a waste area associated with the military plutonium production operation at Chelyabinsk (Russia). A powerful chemical explosion occurred in a concrete waste storage tank containing 80 tones of fission products and MAs. Failure of the tank's cooling system caused a mostly solidified mixture of sodium acetate and sodium nitrate to ignite. About 20 million curies of radioactivity were released contaminating an area of 15,000 km². For comparison, the Chernobyl reactor accident released about 50 millions curies. This Soviet era accident was not officially reported to the IAEA for some 30 years.

There is another type of accident unique to nuclear facilities known as a criticality accident. This occurs when a mixture of nuclear materials and usually water is put together in a confined space accidentally creating the conditions for a chain reaction. There have been more than 30 such accidents since the beginning of nuclear processing and a particularly severe one took place at Tokai, Japan in 1999. A company known as JCO was preparing enriched uranium fuel and instead of using the carefully designed system of pumps and vessels put in place to avoid criticality, the workers routinely added uranium solutions to a vat with buckets. On the occasion in question this practice resulted in a chain reaction, which went on for some 20 h. Two workers died from the radiation sickness and another one was badly injured. Since this particular building did not have a containment system, residents of the surrounding area were exposed to levels of radiation that were later assessed not to be harmful. The causes of this easily avoided accident were incompetence and stupidity.

The Tokai experience illustrates the reality that even in an advanced industrial country, no amount of safety culture or regulatory supervision can completely eliminate the possibility of accidents. Hence, nuclear facilities such as reprocessing plants must be built to contain and limit any accidental releases of radioactivity within the plant itself. The technology to do this is now widely available and, if deployed, safety although it must always be an important concern would probably not form a technical obstacle to building additional reprocessing plants.

Impact of transmutation on waste management and disposal

In general, the sources of secondary wastes from the MA separation methods are the following:

- Aqueous liquid waste from solvent cleanup,
- α -contaminated solvent,
- Condensate from evaporation and denitration steps,
- Scrub liquors from valency adjustment (in case of Np),
- Different liquid and solid wastes from Np, Am (Cm) product preparation,
- Solid contaminated wastes from Np, Am-Cm target preparation.

Elimination of ^{237}Np during the advanced reprocessing operations will slightly increase the secondary waste as the stripping of Np from the Np-Pu stream takes place in the second Pu-purification cycle. However, most of these waste streams can be recycled to the HLW acid recovery step and mixed with the concentrated HLW. Very little is presently known about the secondary waste generation resulting from the introduction of Am-Cm separation methods.

Once separation-conditioning and target fabrication processes have been developed and demonstrated on a pilot scale, transmutation by irradiation in dedicated facilities can theoretically be envisaged. Since this implies also the simultaneous development of dedicated irradiation facilities (FRs or ADSs), it will take several decades before this option could become available. However, the impact of the transmutation option starts as soon as the targets and/or fuels are ready for irradiation, which may be much earlier than the implementation of dedicated irradiation facilities. The safety and security of this option requires much attention (OECD-NEA, 2002, 2001; IAEA, 2004; Wydler and Baetsle, 2000).

Transmutation of separated MA and, more generally, TRUs makes their handling and storage operations in engineered storage facilities more difficult. It increases the heat load of the waste and generates secondary waste. These drawbacks have to be weighed against the very long term benefit of decreasing the dose to humans in the very distant future (millions of years). However, it gives the present generation an ethical guarantee that the present nuclear legacy will not unduly burden future civilizations. By transmuting TRUs the very long term hazard will be decreased, but it still has to be compared with the natural actinide decay chains of uranium (depleted and reprocessed).

Proliferation risk and proliferation resistance of nuclear waste management options

Proliferation risk and proliferation resistance of nuclear waste management options have to do with protection measures of fuel cycle facilities and with presence of nuclides of concerns in reprocessing streams. Inherently avoiding fuel cycle scenarios with separated plutonium streams and keeping TRU together mitigates the associated risks. Furthermore, high radioactivity levels of reprocessed used fuel streams poses tremendous accessibility challenges. Research efforts are in progress to enhance waste stream characterization capabilities (National Research Council, 2011).

Background

From currently 6.7 billion people, the world's population is expected to grow to over 9 billion by 2050. As recognized in the United Nations Resolution 70/1 "Transforming our world: the 2030 Agenda for Sustainable Development" (United Nations, 2015), providing "universal access to affordable, reliable and sustainable energy" and in particular to reliable electric energy, is central to human development, social stability and even world peace.

When looking ahead at the next 50 years or so, it should be reminded that currently, about 2.8 billion people are still lacking modern energy services (International Energy Agency, 2017), and more than one billion do not have access to electricity. Not only the growth of worldwide population, but also the economic growth in developing countries will lead to further increase of the demand for energy. There will most likely be diverse energy sources co-existing side by side. These various sources will have to be integrated into "smart" (i.e. efficient and flexible) energy systems catering to various applications and needs. The share of fossil energy sources (mostly coal and natural gas) will decrease, albeit slowly, while its impact on the Green House Gas (GHG) emissions will be mitigated by the introduction of carbon capture technologies.

The seriousness of climate change and the related importance of having abundant carbon-free energy sources available to replace the world's current dependency on GHG emitting energy sources are understood. Therefore, it is recognized (United Nations, 2000) that a paramount objective of sustainable energy policy is the need to reduce GHG emissions, in particular carbon-dioxide.

Since 1971, the release of approximately 60 Gt of carbon-dioxide has been avoided by nuclear energy generation (International Energy Agency, 2014). Currently, nuclear energy is avoiding the release of about 1.7 Gt carbon-dioxide per year. While producing no carbon emissions during electricity generation, nuclear energy has a very small life-cycle carbon footprint originating from fossil fuels used during mining, manufacturing, and transportation of materials and components.

Moreover, nuclear energy can help smooth the integration of renewable, albeit intermittent capacity into electric grid systems. Consequently, going forward, the IEA projects that nuclear will play a cornerstone role in climate-friendly scenarios. For the strategy that limits global temperature increase to 2 °C, nuclear capacity would more than double by 2050, representing 17% of worldwide electricity production. In this scenario, nuclear would be the technology that is maximizing cumulative carbon-dioxide emissions avoidance (International Energy Agency, 2015).

In spite of its potential, the current situation of the nuclear energy sector is difficult. The nuclear energy share of global primary energy production (currently just over 4%) is steadily shrinking, as is also the worldwide nuclear energy share of commercial electricity production (International Energy Agency, 2019a). New build projects are almost entirely limited to a handful of countries in Asia, and to Russia. New build projects require high investments, and their financing is introducing considerable financial risks. Therefore, fewer investments are canalized into the nuclear sector. This is also the case (with few exceptions) for public investment related to nuclear energy Research and Development (R&D).

There are massive global investments in alternative (renewable) energy concepts and the development of the related infrastructure. For example, a recent IEA publication (International Energy Agency, 2019b) is forecasting a 50% increase of the global renewable power capacity (corresponding to 1200 GW) over the 2019–2024 five-year period. This increase will be realized mostly thanks to the implementation of distributed photo-voltaic technology installed on private, commercial and industrial structures. Contrasting this trend, nuclear energy is considered by many as "not renewable" and is losing its ground as the sustainable, practically zero-carbon footprint option it really is. The reasons for this overall negative assessment are a combination of socio-economic and technological perceptions. Nuclear energy is being perceived by many as a complex and expensive technology that is no longer necessary, given the advent of "renewable" solar and wind energy; as unacceptably dangerous (since the Fukushima Dai-ichi accident); and also as polluting (radioactive waste). Moreover, in many administrative, political, financial and academic circles, proponents of nuclear energy are met with distrust, seen as lacking social responsibility, accountability, and transparency.

More specifically, there are various barriers faced by innovative nuclear research, development, demonstration and deployment (R&D&D&D) efforts, e.g. (International Framework for Nuclear Energy Cooperation/Nuclear Energy Agency, 2016): negative social and political perception of nuclear energy safety characteristics; uncertain and changing political support coupled with explicit governmental support for renewables in some countries; insufficient carbon pricing to promote nuclear investments along with

electricity market structures (unstable electricity prices in liberalized markets) that do not provide investment signals for low-carbon technologies; the long-term nature of capital investments in the nuclear sector, along with very high costs, technical risks, as well as past and current nuclear built budget and schedule overruns.

In order to reverse these perceptions and the worldwide continuous decline in funding for long-term research and technology development that these perceptions provoke, it is imperative that the nuclear energy option regain public trust and acceptance by continuously demonstrating social responsibility and uncompromisingly adopting the wider sustainability criteria – environmental soundness, safety, security of supply, costs, and non-proliferation (Bisconti, 2021; Golay, 2021; Parsons, 2021; Rothwell, 2021; Ingersoll, 2021; Shellenberger, 2021; Kadak, 2021; Cheng, 2021; Hore-Lacy, 2021).

Based on the recognition that, on the one hand side, nuclear energy is losing political support and, more fundamentally, the understanding of and legitimacy with a wide-ranging fraction of society, and firmly convinced, on the other side, that nuclear energy, as a practically zero-carbon footprint option, has a crucial role to play as part of a worldwide long-term sustainable energy mix, it must be concluded that radically novel nuclear energy systems must be developed, offering options that are both acceptable to society and attractive to the investor in the energy market. Since the industrial revolution, it was arguably proven that, in all technological areas, such a goal can only be achieved through innovation, which, in turn, is achieved through R&D to fill knowledge gaps, adapt the technology to new requirements, and foster inventions. On the other hand, it must be acknowledged that the required investments to resolve the technological barriers and R&D risks are large and beyond the means of most individual organizations and many countries. This recognition provides the basic rationale for the R&D&D&D efforts undertaken within the framework of the Generation IV International Forum (GIF) to develop “4th generation” (GEN IV) nuclear energy systems.

Section 3 of the “New Encyclopedia of Nuclear Energy” is presenting the worldwide status of advanced and innovative nuclear energy systems research and technology development. It is structured around four topical blocks and one cross-cutting block. The four topical blocks comprise the

- i. Six GEN IV systems
- ii. Advanced LWRs
- iii. Breed-and-Burn (B&B) reactors
- iv. Small and Medium-sized Reactors (SMRs).

The cross-cutting block comprises

- i. Advanced modeling and simulation
- ii. Deployment challenges and opportunities.

The fluoride salt cooled high temperature reactor concept and the micro reactor concept can also be considered, for practical reasons, to fall into the SMR category.

Status of GEN IV nuclear energy systems development

Introduction

The GIF is providing a multinational collaborative framework for R&D efforts aiming at establishing the feasibility and performance capabilities of innovative GEN IV nuclear energy systems that meet the objectives of improved sustainability, economics, safety and reliability, as well as proliferation resistance and physical protection (GIF, 2014).

The 12 GIF partners (Australia, Canada, European Union, France, Japan, Republic of Korea, People’s Republic of China, Russian Federation, South Africa, Switzerland, United Kingdom, and United States) actively participating in the GIF are pursuing technological innovation and advanced nuclear reactor design efforts toward meeting the aforementioned objectives.

The R&D focus of the GIF partners is documented by their respective commitment to the various GIF System Arrangements (SA), Memoranda of Understanding (MOU), and/or Project Arrangements (PA), specifically for the

- Sodium-cooled Fast Reactor (SFR): European Union, France, Japan, Republic of Korea, People’s Republic of China, Russian Federation, and United States
- Very-high Temperature Reactor (VHTR): Australia, Canada, European Union, France, Japan, Republic of Korea, People’s Republic of China, Switzerland, and United States
- Gas-cooled Fast Reactor (GFR): European Union, France, and Japan
- Molten Salt Reactor (MSR): Australia, European Union, France, Russian Federation, Switzerland, and United States
- Lead-cooled fast reactor (LFR): European Union, Japan, Republic of Korea, Russian Federation, and United States)
- Supercritical Water-cooled Reactor (SCWR): Canada, European Union, Japan, People’s Republic of China, and Russian Federation.

The GIF partners are investigating nuclear energy cost reduction potentials by studying simplified designs that are addressing new market opportunities and delivering (in addition to electricity) heat, hybrid and dispatchable energy systems, as well as by increasing thermal efficiencies. The latter is achieved by adopting high-temperature coolants like liquid metals, helium, liquid salts, or super critical water. In addition to increasing thermal efficiencies, such coolants are also widening the application range of nuclear energy to industrial heat applications, thus displacing industrial fossil fuel burning. With regard to enhanced sustainability, GIF’s

GEN IV nuclear energy systems, when combined with innovative fuel recycling options, are improving uranium utilization by a factor of 70–100, and also reducing both volume, radiotoxicity and heat load of the waste to be disposed of in the final deep geological repository.

Recognizing the strategic importance of hybrid energy systems with an ever-increasing share of intermittent energy sources and demanding energy storage and supply flexibility, the GIF partners are addressing dispatchable energy concepts in both electricity and heat applications.

With regard to safety, GIF's GEN IV nuclear energy systems are maintaining and improving the current stringent safety standards. Moreover, and as an example for GIF's institutional innovation efforts, the GIF partners are pursuing activities aiming at the harmonization of regulatory requirements (Nuclear Energy Agency, 2011). By the same token, a GIF Task Force on defining safety design criteria and safety guidelines for GEN IV sodium cooled fast reactors designs is striving to engage regulators and share results of the safety research conducted in the field of such advanced GEN IV reactor concepts.

Another example for the institutional and organizational innovation pursued within the GIF framework is the effort to investigate new ideas and business models for engaging private capital in the development of small modular reactors and GEN IV systems. With this, the partners in the GIF collaboration framework are acknowledging the reality of strong support coming from venture capital (proof of investment leaders' confidence in the potential of the nuclear energy option) to numerous start-up companies that are developing innovative SMR designs.

GEN IV nuclear energy systems

The original GIF Roadmap (GIF, 2002), which was updated in 2014 (GIF, 2014), identified six nuclear energy systems (viz. the Sodium-cooled Fast Reactor (SFR), the Very-high Temperature Reactor (VHTR), the Gas-cooled Fast Reactor (GFR), the Molten Salt Reactor (MSR), the Lead-cooled fast reactor (LFR), and the Supercritical Water-cooled Reactor (SCWR) that were the most promising to meet the stated objectives (improved sustainability, economics, safety and reliability, as well as proliferation resistance and physical protection) for a nuclear system to qualify as "4th generation."

Fig. 1 (GIF, 2018) provides an overview of the generations of nuclear power: from the early prototype reactors to the revolutionary designs of the "fourth generation." The time ranges indicated in this figure correspond to the design and the first deployments of the respective reactor generation. For a more detailed historical overview, the reader is referenced to (Schwageraus, 2021).

Table 1 (Pioro, 2016) provides a summary of the main design characteristics of the various reactor concepts that are being investigated by the GIF partners.

Each of the GEN IV nuclear energy systems includes the nuclear reactor, its energy conversion systems, and the respective fuel cycle technologies.

Fig. 1 The Nuclear Power Reactor Generations.

Table 1 GEN IV nuclear energy systems: main design characteristics.

	Neutron System spectrum	Fuel type	Coolant	Outlet temperature [°C]	Electrical power rating [MW]	Energy conversion cycle	Thermal efficiency [%]	Fuel cycle
SFR	Fast	Mixed U-Pu-minor actinide oxide or metal; U-Pu-minor actinide-Zr Alloy	Sodium	500–550	50–150 300–1500 600–1500	Indirect steam Rankine; 40 indirect supercritical pressure carbon- dioxide Brayton gas turbine		Closed
VHTR	Thermal	TRISO-coated particles (pebbles or compacts)	Helium	750–950 (ultimately 1000)	250–300/thermal power 10–625 MW in co-generation mode	Indirect Rankine steam; > 55/>80 direct helium Brayton; (electrical indirect helium- nitrogen cycle; hydrogen co- generation mode)		Open (closed fuel cycle potential with U-Th fuel)
GFR	Fast	Mixed U-Pu oxide /carbide/nitride	Helium	850	1200	Indirect combined (helium-nitrogen and steam circuit); direct Brayton helium turbine; indirect Rankine steam	> 50	Closed
MSR	Thermal Fast	U, Th-U fluorides U-Pu, Th-U, Pu fluorides	Same as fuel (fluoride salts)	700–800	1000	Brayton gas turbine (carbon-dioxide); indirect steam Rankine	50	Closed
LFR	Fast	Mixed U-Pu oxide; Mixed U-Pu-nitride (both options with/ without minor actinides)	Lead	480–570	20–180 300–1200 600–1000	Indirect Rankine steam / super-heated steam; gas turbine Brayton (carbon-dioxide)	41–43	Closed
SCWR	Thermal Fast	U-oxide; Th-Pu oxide Mixed U-Pu oxide	Water	510–625	300–700 1000–1500	Direct super-heated once-through steam	45–50	Open Closed

For illustration purposes, [Figs. 2–7 \(Pioro, 2016\)](#) are showing overview sketches of some GEN IV nuclear energy systems.

While the original high-level four GEN IV objectives remain valid, the updated 2014 GIF Roadmap acknowledged that the GEN IV nuclear energy systems (i) have the primary mission of generating power, (ii) have the capability to deliver non-electric products like process heat and hydrogen, (iii) aim at minimization of waste, and (iv) offer the flexibility needed for cost-effective integration into global low-carbon energy systems.

All six systems deliver power. VHTR, GFR, LFR and MSR are higher temperature systems and offer process heat and hydrogen production capabilities. All fast neutron spectrum systems (SFR, GFR, LFR, and the fast SCWR concept) and the MSR offer the capability to transmute actinides and thus are pushing the waste management objective.

Given their role in a hybrid energy world with an ever-increasing share of intermittent energy sources, the GEN IV systems will have to respond to broad flexibility requirements in terms of operational flexibility (compatibility with hybrid systems, island mode operation, diversified fuel use), deployment (scalability, siting, constructability), and energy products (power, process heat). Last but not least, in an effort to enhance market attractiveness, a metrics to evaluate the “flexibility” and design maturity of GEN IV nuclear energy systems is needed that will also take into consideration the impact on the deployment of GEN IV nuclear energy systems of factors other than cost (e.g. electricity market characteristics, national policies, products/services requirements, etc.) ([Electric Power Research Institute, 2018](#)).

The following sub-sections are providing brief descriptions of the design characteristics and major operational and safety characteristics of the six GEN IV systems. Detailed information, in particular in terms of the major design objectives, as well as the challenges and opportunities on the path to commercialization can be found in [Heidet \(2021\)](#), [Fütterer et al. \(2021\)](#), [Hatala \(2021\)](#), [Ignatiev \(2021\)](#), [Alemberti \(2021\)](#), and [Zang and Huang \(2021\)](#) for the SFR, VHTR, GFR, MSR, LFR, and SCWR, respectively, as well as in ([Sadhankar, 2021](#)). Moreover, the reader wanting in-depth technical immersion into the GEN IV systems is referred to ([Pioro, 2016](#)).

Sodium-cooled fast reactor (SFR)

The salient characteristic of the GEN IV sodium-cooled fast reactor (SFR) is its capability to utilize the transuranic actinides for energy production. This permits vastly extending the primary energy resource uranium, and, at the same time, reducing the

02-GA50807-03

Fig. 2 The pool-type GEN IV SFR design with an indirect steam turbine Rankine power cycle.

Fig. 3 The prismatic fuel block GEN IV VHTR reactor concept with hydrogen co-generation.

Fig. 4 The GFR GEN IV concept with direct gas turbine Brayton power cycle.

volume, radiotoxicity of, and heat load in the waste to be disposed of in the final geologic repository. To meet these fuel cycle management objectives of regenerating fissile material and enhancing the utilization of minor actinides, the SFR must operate in a closed fuel cycle (Grenèche, 2021). Accordingly, the development and qualification of safe and cost-effective fuel recycle technologies is a major challenge addressed by the GIF partners on the road toward industrial deployment of SFRs.

The unique characteristics of the SFR are due to the fact that it operates with fast neutrons. It is cooled by liquid sodium and lacks moderating materials. Given the cooling properties of sodium, the coolant volume fraction in the core of the SFR core is low compared with a light water-cooled thermal reactor, while the core power density as well as specific power are much higher. Because of the chemical reaction of sodium with oxygen, the SFR requires a sealed coolant system which guarantees an oxygen-free environment that is preventing corrosion.

For the power conversion system, water/steam, nitrogen, and supercritical carbon-dioxide are considered as working fluids. SFR power rating options range from 50 to 300 MWe small modular reactors to larger plants of up to 1500 MWe.

There are two fuel recycle technology options being pursued, viz. the advanced aqueous, and the pyrometallurgical reprocessing option (Taylor, 2021; Bourg, 2021; Miguiditchian, 2021). Advanced mixed (uranium-plutonium-minor actinides) oxide, and mixed metal alloy are the primary fuel types for the advanced aqueous reprocessing option, and the pyrometallurgical reprocessing option, respectively. Mixed nitride fuel that can be recycled by both advanced aqueous and pyrometallurgical reprocessing methods is also being considered.

Fig. 5 MSR concept with indirect Brayton power cycle.

The major safety features of the GEN IV SFR allowing to achieve a high safety level through inherent and passive means and to accommodate transients and bounding events with significant safety margins, are long thermal response time, reasonable margins to coolant boiling, a primary system that operates near atmospheric pressure, and an intermediate sodium system between the radioactive sodium in the primary system and the power conversion system.

Very-high temperature reactor (VHTR)

The salient characteristics of the GEN IV very-high temperature reactor (VHTR) are the fully ceramic coated TRISO particle fuel, the graphite moderator, and the helium coolant.

The TRISO fuel is composed of small kernels of ceramic fissile material (UO_2 or UCO) that is coated with pyrocarbon, silicon carbide, and pyrocarbon layers. Many experimental and operational performance tests have proven that the three-layer coating design provides an excellent barrier against fission product release under both normal operational and accident conditions. The kernels are surrounded by a porous carbon buffer and assembled either into pebbles or prismatic blocks. The shape of the VHTR fuel defines the two design concepts being pursued, viz. the pebble-bed core and the prismatic-block core.

Various engineering-scale tests and the operation of prototype high temperature gas-cooled reactors have demonstrated the VHTR concept's inherent safety characteristics. All VHTR cores are designed to ensure passive decay heat removal.

The long-term objective of the GEN IV VHTR development efforts is a reactor delivering heat at about 850°C (that would require a reactor outlet temperature around 1000°C) to be used by a hydrogen production facility (based on, e.g., the sulfur-iodine thermochemical process). R&D efforts are also pursued to develop innovative heat transfer technologies allowing to reduce the reactor outlet temperature requirements (also in view of ongoing efforts to reduce the hydrogen production temperature requirements).

In parallel, the recognition that process heat in form of steam at less than 600°C is currently representing a considerable market (globally in the order of several hundred GWth, almost entirely supplied by fossil fuelled power plants), short-term efforts are pursued to develop less ambitious high temperature gas cooled reactors (having core outlet temperature around 750°C) for industrial applications, as a zero-carbon alternative to the fossil-fuelled power plants.

Accordingly, in the short-term, GEN IV VHTR concepts could be designed having core outlet temperatures in the range 700 to 950°C (for which there are available high-temperature alloys employed in heat exchangers and other reactor metallic components) to deliver both power and process heat. In the long-term, however, higher core outlet temperatures would require the development of innovative materials (e.g. ceramics, super-alloys, etc.).

Fig. 6 LFR concept with indirect Brayton power cycle.

Gas-cooled fast reactor (GFR)

The salient characteristic of the GEN IV gas cooled fast reactor (GFR), which is put forward as a longer-term alternative to the sodium cooled fast reactor, is its single-phase inert gas coolant. GFR's coolant is chemically inert, does not dissociate or become activated in the neutron field, and is transparent. This latter characteristic, in addition to simplifying coolant handling, is facilitating inspection and repair operation.

The power density of the GFR core is relatively high. Its core outlet temperature is also high, in the range of 800–850 °C, opening up non-power applications in addition to the sustainability improvements linked to the closed fuel cycle.

The GFR coolant void coefficient, while still positive, is small, and the core's safety characteristics are dominated by the negative Doppler feedback.

The reference concept for GFR is a 2400 MWth nuclear power plant featuring a break-even core with 850 °C outlet temperature, which allows adopting an indirect combined gas-steam cycle that is achieving approximately 48% efficiency. The primary circuit with three loops is contained within a secondary pressure boundary that constitutes a guard containment against depressurization accidents. The heat is converted into electricity in the indirect combined gas-steam cycle with three gas turbines and one steam turbine. A heat exchanger transfers the heat from the primary helium coolant to a secondary gas cycle containing a helium-nitrogen mixture that drives a closed cycle gas turbine. The waste heat from the gas turbine exhaust is used to raise steam in a steam generator that is then used to drive a steam turbine.

The major challenges for the GFR are linked to the development of the fuel, cladding and structural materials meeting the requirements of a high-power density, high outlet temperature fast neutron core (i.e. 1000 °C normal operation clad temperature, no fission product release at 1600 °C clad temperature during a few hours, ensuring the core cooling capability up to 2000 °C clad temperature). The reference GFR core design consists of an assembly of hexagonal fuel elements, each consisting of ceramic-clad, mixed-carbide-fuelled pins contained within a ceramic hex-tube. Currently, the reference material for both the pin clad and the hex-tubes is silicon carbide fiber-reinforced silicon carbide (SiCf/SiC).

Fig. 7 The SCWR GEN IV concept with direct steam turbine Rankine power cycle.

The GFR developers are considering that an experimental reactor rated at less than 100 MWth is needed to demonstrate the GFR viability and to qualify specific GFR technologies such as the refractory fuel elements and the specific safety systems, in particular the decay heat removal function. Current activities within the GIF framework are focused on this objective.

Molten salt reactor (MSR)

Molten salt reactors (MSRs) are broadly grouped in two categories: reactors in which a fuel salt containing fissile material that is fissioning in the core is circulated through the primary system serving both purposes – fissile material and coolant; and reactors fuelled with solid fissile material in which the coolant is a molten salt. In both cases, the neutron spectrum can be thermal, epithermal or fast. Thermal neutron spectrum MSRs usually employ fluoride salts, and their design relies on solid moderator materials within the core. Fast neutron spectrum MSRs do not need moderator materials in the core and can be designed employing fluoride or chloride salts.

The partners collaborating on MSR within the GIF framework are pursuing R&D for both MSR types. The salt-fuelled MSR R&D efforts are concentrated on fast neutron spectrum concepts, with the objective of combining the advantages of fluoride molten salts (viz. low pressure, high temperatures, optical transparency) with the advantages of fast neutron systems (viz. improved fissile utilization and waste management).

R&D on fast neutron spectrum MSRs is focused on three concepts: the 1000 MWe MOSART design with the main objective of recycling actinides; the 1400 MWe thorium-molten-salt fueled MSFR; and the MCFR design that has a very hard neutron spectrum and the objective to require fissile seed only for the start-up core and run without the need to separate the fissile material from the circulating fuel salt.

In theory, the fast neutron spectrum MSRs have a number of advantageous characteristics, when compared to solid fuel fast reactors: large negative reactivity coefficients, lower fissile inventories, a homogeneous isotopic composition of the fuel, no radiation damage constraints on attainable fuel burnup, no used nuclear fuel, no requirement to fabricate and handle solid fuel.

In terms of a solid fuel reactor cooled by molten salt, R&D efforts are focused on the fluoride salt cooled high temperature reactor (FHR). The FHR has a near-thermal neutron spectrum and is adopting a once-through fuel cycle based on low enriched uranium. It relies on ceramic fuel and on low pressure fluoride salt cooling. The FHR is designed to have a high temperature power cycle and fully passive decay heat removal characteristics (Fratoni, 2021).

There remain considerable challenges in terms of demonstrating the viability and performance of MSR concepts, requiring long-term research and technology development efforts addressing, e.g.: salt physical, chemical and thermodynamic properties; system design and safety studies; development of advanced materials, studies of their compatibility with molten salts, and their performance in high neutron and temperature fields; corrosion and tritium release prevention technologies; development of efficient techniques for gaseous fission products extraction from the fuel salt; chemical processing flowsheets; development of safety, safeguards, security and proliferation resistance approaches applicable to liquid-fuelled reactors.

Lead-cooled fast reactor (LFR)

The salient characteristics of the GEN IV lead cooled fast reactor LFR are its fast neutron spectrum (comparable to the SFR) and closed fuel cycle aiming at improved fissile utilization and waste management. Given the properties of the lead coolant (very high boiling temperature, chemically inert, operating at near atmospheric pressure), the LFR has the potential to achieve considerable design simplification compared to the SFR and very good safety characteristics.

The R&D efforts within the GIF framework are focused on three LFR options: a large 600 MWe reactor (ELFR) meeting central station power generation objectives; an intermediate size 300 MWe reactor (BREST-OD-300), and a small transportable reactor rated in the 10–100 MWe range Small Secure Transportable Autonomous Reactor (SSTAR) featuring very long core lifetime and offering the possibility to provide power and heat to remote locations. For all the LFR options, the objective is to achieve at least 42% energy conversion efficiency.

The ELFR and the BREST-OD-300 designs feature secondary water loops with superheated once-through steam generators and a steam Rankine cycle achieving energy conversion efficiency well above 40%. The SSTAR design features a supercritical carbon-dioxide power conversion system in a direct Brayton cycle and achieves a similar level of efficiency.

Design simplifications like the elimination of the intermediate cooling system and the adoption of reduced height core components allow the reduction of both capital cost and construction time, thus improving the economics of the LFR.

The BREST-OD-300 reactor uses nitride fuel and adopts a closed fuel cycle with the nitride fuel manufacturing and reprocessing facilities co-located at the reactor site. The BREST-OD-300 design adopts an integrated layout with a multilayer reinforced metal-concrete vessel. The coolant and the main primary circuit components are located in this vessel. There are no coolant valves in the primary circuit. Emergency cooling is ensured by convective circulation, removing the heat directly from the primary circuit to air as the ultimate heat sink. Building on the properties of the lead coolant and of the high-density, heat-conducting uranium-plutonium nitride fuel, the BREST-OD-300 design ensures efficient fuel utilization. In tandem with a small fuel temperature power reactivity effect, this allows reactor operation with a small reactivity margin, which constitutes an important prevention measure against unprotected transient overpower accident initiators. Loss-of-coolant type accidents are prevented by the aforementioned integrated reactor layout.

The major design and operational features of the reference 20 MWe SSTAR design are molten lead coolant, nitride fuel containing transuranic elements, fast neutron spectrum, natural circulation, and transportable reactor vessel. These design characteristics constitute an unique approach to proliferation resistance by enabling a long core lifetime, autonomous load following, simplicity of operation, reliability, transportability, and a high degree of passive safety.

Supercritical water-cooled reactor (SCWR)

The salient characteristics of the GEN IV super-critical water-cooled Reactor (SCWR) is the high temperature, high pressure water coolant above the thermodynamic critical point of water (374 °C, 22.1 MPa).

Most SCWR designs are developed for power generation and are rated above 1000 MWe. The SCWR operates at pressures of about 25 MPa and reactor outlet temperatures up to 625 °C. The SCWRs could generate electricity with thermal efficiencies ranging from 43 to 48%, as compared to 32% for the current fleet of nuclear reactor systems. Moreover, the relatively high SCWR core outlet temperature offers the opportunity for co-generation, such as hydrogen production. The SCWR coolant does not change phase, allowing the design to adopt the direct power cycle without moisture separator, reheaters and recirculation pumps as in the boiling-water reactors, or steam generators as in the pressurized light-water and heavy-water cooled reactors. These design simplifications are vastly reducing the size of the SCWR nuclear power plant, allowing a balance-of-plant configuration that is the same as that of a fossil-fired power plant.

Because of the potential advantages of the SCWR (viz. improved economics due of the high thermodynamic efficiency, and the potential for plant simplification), the GIF partners are pursuing R&D for two types of SCWR concepts: the pressure-vessel and the pressure-tube concept. Other than specifics of the core design, these concepts have many similar features (viz. the outlet pressures and temperatures, thermal neutron spectra, steam cycle options, materials, etc.). Improvements in the areas of safety, sustainability, proliferation resistance and physical protection are being pursued by considering several design options using thermal and fast spectra, including the use of advanced fuel cycles.

The SCWR has a long-term vision for light water reactors that requires significant development in technical areas (such as materials, chemistry, thermal hydraulics, neutronic, instrumentation, control, etc.). At the same time, the SCWR benefits from the interest in LWRs as well as an established technology for supercritical water power cycle equipment in the fossil-fired power industry. The

path forward for the SCWR efforts within the GIF framework consists in demonstrating the SCWR viability and designing and operating a prototypical fuelled test loop, thus preparing the grounds for designing and deploying a prototype reactor. The main R&D activities include system Integration and assessments, materials and chemistry, as well as thermal hydraulics and safety analyses.

Glossary

BG Breeding Gain is defined as $BR-1$; that is the measure of the extra fissile material in the used nuclear fuel relative to the fissile inventory in the initial fuel loading.

Breeding ratio (BR) Defined like the CR and usually applied to situations in which the CR is equal to or larger than unity.

Conversion ratio (CR) The ratio of fissile material inventory in the used nuclear fuel to the fissile material inventory loaded into the core. Usually used when this ratio is smaller or equal to unity.

Electron-volt (eV) A measure of the neutron j = kinetic energy; $MeV = 10^6$ eV.

Gigawatt-day per initial ton of heavy metal (GWd/t) A measure of the amount of fission energy generated per unit fuel weight.

Reactivity and Reactivity Coefficients “Reactivity” is a term used to denote the extent of the deviation in the core effective multiplication factor (usually denoted as k_{eff}) from its value at a just critical state (at which state $k_{eff} = 1.0$ and the fission-rate is constant). A positive reactivity Coefficient implies that the ratio of the rate of neutron production to the rate of neutron losses (k_{eff}) is increasing due to a unit change in a performance characteristic such as temperature or density. One of the necessary characteristics for a reactor to be inherently safe is that the combined effects of all possible changes in reactor conditions due to a power increase will result in a negative reactivity feedback.

Introduction

Sodium-cooled fast reactors (SFR) are one of the reactor technologies part of the Generation IV (GEN IV) reactors (GIF, 2018), in Fig. 1. They are considered advanced reactors as opposed to the water-cooled reactors currently used commercially across the world based on their enhanced safety characteristics and additional capabilities. Compared to other advanced reactors, SFRs are one of the most mature technology as they have benefited from many years of technology development and reactor operation. Their benefits have been successfully demonstrated around the world through construction and operation of a number of SFRs. However, early nuclear energy history in the United States led to advancing water-based nuclear reactor systems more than sodium-based nuclear reactor systems.

A bit of history

As with most of the early nuclear energy history, this is taking us to the United States. Liquid metal cooled reactors history starts only a few years after the successful demonstration of the feasibility of a sustainable fission chain reaction in Chicago Pile 1 (DOE, 1982), in 1946, with the Clementine reactor. This reactor was cooled with mercury as it is in its liquid phase at room temperature and atmospheric condition. The Clementine reactor (IAEA, 2013) paved the way to sodium-based systems and led to the construction of the Experimental Breeder reactor (EBR-I) in 1951 (Lichtenberger et al., 1953). EBR-I designed and operated by Argonne National Laboratory, and sited in the state of Idaho, was cooled with a mixture of sodium and potassium. It was the very first nuclear reactor to produce electricity as captured in the photo shown in Fig. 2.

Fig. 2 First light bulbs powered by nuclear energy from EBR-I. https://commons.wikimedia.org/wiki/File:First_four_nuclear_lit_bulbs.jpeg

Shortly after EBR-I, the U.S. Navy which had gained a significant interest in nuclear power and spearheaded a lot of the early technology development, ordered in 1952 the development of a nuclear-powered submarine relying on a SFR. The U.S.S. Seawolf (SSN-575) resulted from this effort and was the second nuclear-propelled submarine in the world, successfully operating for its full planned 30-year life (Friedman, 1994). However, initial challenges with having a sodium system submerged in a water environment led to focusing development efforts on a water-based nuclear reactor for naval applications. With the sodium-cooled systems being less mature than water-cooled systems, commercial application of nuclear power logically leveraged the water-cooled reactor technology due to its higher maturity.

Yet, a subsequent number of experimental, research or demonstration SFR were designed, built and operated around the world. Countries like the United States, the United Kingdom, France, Germany, Russia and Japan established programs to support development of this reactor technology. With many SFRs built and operated (IAEA, 2007), some of these landmark efforts included the

Experimental Breeder Reactor II (EBR-II) in the United States (IAEA, 2013), the Phenix reactor in France (Sauvage, 2006) and the BOR-60 reactor in Russia (Trojanov and Rinejsjij, 1992).

EBR-II, shown in Fig. 3, was built in the United States in 1958 and underwent its final shutdown in 1998. It was a 62.5 MWth/20 MWe pool-type reactor. It was the successor to the very first SFR, EBR-I, and aimed at demonstrating several of the capabilities

Fig. 3 EBR-II primary vessel and its internals (Keeton, 1984).

enabled by that reactor technology. While initially operated as an experimental reactor, it served as a demonstration reactor for a large fraction of its life. In particular, it supported demonstrated fuel reprocessing, inherent safe behavior of SFRs—including unprotected transients, and possible use of various fuel forms (Imel, 2021). EBR-II was the stepping stone to the Advanced Liquid Metal Reactor (ALMR) (Hardy et al., 1992), part of the Integral Fast Reactor (IFR) project (Till and Chang, 2011). With the ALMR having been developed by Argonne National Laboratory in collaboration with General Electric, when the IFR project got canceled in 1994 due to political reasons, the ALMR concept survived through the Power Reactor Innovative Small Module (PRISM) designed by General Electric Hitachi (Triplett et al., 2012).

The Phenix reactor was built in France in 1968 and underwent its final shutdown in 2009. It was preceded by the Rapsodie reactor (Vautrey and Zaleski, 1962), the first French SFR. Similarly to other countries, Rapsodie was an experimental reactor serving as a stepping stone for the Phenix reactor, which operated as a demonstration reactor. Phenix was a 563 MWth/255 MWe pool-type reactor, although during the latter part of its operational life its power level was limited to 350 MWth/145 MWe. It first served to demonstrate electricity generation at a large scale, and subsequently also served to demonstrate transmutation of nuclear wastes with a SFR. The successor to Phenix was Superphenix (Schneider, 2009), built in 1976. While it operated for many years, Superphenix suffered from poor public opinion and political support, which precipitated its shutdown and closure in 1998, way ahead of its intended lifetime.

The BOR-60 reactor, shown in Fig. 4, was built in Russia in 1964 and is still operating in 2021. It was preceded by the BR-5 and BR-10 reactors (Trojanov and Rinejsij, 1992) which served as stepping stone to gradually increase the power level of the Russian SFRs. BOR-60 is a 60 MWth/12 MWe loop-type experimental reactor the main mission of which is to provide irradiation services to enable nuclear fuel and material development and qualification, benefiting advanced reactor technologies. It also served studying

various steam generator technologies for electricity production. BOR-60 enabled development of subsequent BN-600 demonstration SFR (Trojanov and Rinejsijj, 1992) and the BN-800 commercial SFR (Krivitski, 2001).

Overall, many SFRs succeeded EBR-I and have been developed and operated by various countries. They served to demonstrate the potential applications and benefits of SFRs. These include, but are not limited to, their ability to be passively safe, to significantly increase resource utilization, to take advantage of used fuel, to consume actinides, and to accelerate irradiation testing and qualification for nuclear fuel and materials. Related technologies, such as fuel reprocessing and isotope separation, were also demonstrated in the process.

SFRs remain the most mature and advanced technology among fast-spectrum reactor technologies. At the time of this writing, there are five SFRs operating in the world and one more currently on stand-by as listed in Table 1. Half of these are located in Russia, which include two relatively large size reactors producing sizable amounts of electricity.

SFR basics

Sodium-cooled fast reactors are relying on fast (i.e., unmoderated) neutrons to sustain the chain reaction in the core. In contrast, in light-water cooled reactors and other non-fast reactors neutrons are first moderated before they contribute to sustaining the chain reaction. This means that SFR and other fast reactors should not contain significant amounts of moderating materials as that would reduce the neutrons energy. In particular, any material containing hydrogen, graphite, or beryllium would act as a moderator and is not typically found in the core of a SFR. Water as a coolant is therefore not a viable option but liquid metals (IAEA, 2012) are a potent way to cool fast reactors as they have a high heat capacity and excellent thermal conductivity, without significantly slowing-down the fission neutrons. Furthermore, liquid metals do not require operating the primary coolant system at high pressure to achieve attractive heat transfer and extract the fission heat at high temperature thus enabling high efficiency for conversion into electricity. While many liquid metals have been considered for fast reactors over time, sodium has been the preferred option due to its characteristics and extensive availability. Sodium is in its liquid phase from 97.8 °C to 882.8 °C at atmospheric pressure and is exclusively composed of ^{23}Na in its natural form. It is non-corrosive with materials typically encountered in nuclear reactors, and remains chemically stable even in the event of fuel constituents being mixed into it. The main drawback of sodium is that when exposed to water, and to a lesser extent to oxygen, it undergoes an exothermic chemical reaction. The reaction with water occurs regardless of the temperature, while with oxygen it occurs only at elevated temperatures. This makes controlling humidity and oxygen contents in SFRs of the utmost importance, in a similar way that controlling impurities in light-water reactors is necessary to avoid unwanted corrosion. This is the primary reason driving SFRs to contain an intermediary coolant loop between the primary loop and the steam plant, when applicable, to avoid potential reactions between activated primary sodium and steam. Sodium can be activated by neutron capture ($^{23}\text{Na} + n \rightarrow ^{24}\text{Na}$ that β^- decays into ^{24}Mg with a half-life of ~ 15 h).

Because they rely on fast neutrons to sustain the chain reaction, SFRs are able to use a larger variety of structural materials than light-water reactors (LWR), since the reactivity penalty (i.e., impact on the reactor neutronic performance, or “neutron economy” (Krepel and Losa, 2021)) is orders of magnitude less than in LWRs. Iron-based alloys such as stainless steels are commonly used in SFRs as structural materials as they are very affordable and well understood materials. For the same reasons, discussed in more details in the following paragraphs, isotopes typically considered as neutron poisons (DOE, 1993a,b) in thermal reactors, are mostly inconsequential in SFRs and other fast reactors. Of particular relevance is the ^{135}Xe isotope. This is a well-known fission product isotope, produced as part of the fission reactions, which has an excessively large cross-section in the thermal energy range, Fig. 5, and therefore leads to significant operational constraints for thermal reactors (e.g., limiting power ramp rates, restart availability) (DOE, 1993a,b). For fast reactors, this isotope does not have any impact besides being a fission gas, possibly contributing to fuel swelling, enabling flexible load-following capabilities in fast reactors.

Fast neutrons lead to additional differences with thermal spectrum reactors, two of which are sometimes considered as potential drawbacks. The first one is that a larger fraction of fissile material, that is uranium enrichment in case of low-enriched uranium (LEU), is required to make the core critical. This is not as much of a drawback at it may initially appear because SFRs can operate at a much higher specific power than thermal spectrum reactors, meaning that the power generated per unit mass of fuel is higher than in most of other reactors (Waltar et al. 2012). Also, the fuel in SFRs can be driven up to about twice the burnup levels than in

Table 1 List of currently active SFRs (IAEA, 2007).

Name	Type, coolant	Power, MW	Configuration	Fuel type	Country	Start date
		Thermal/electric
